Unless Otherwise Noted.
* Depth Below Land Surface

Project	WI0637.001	Well	GM-1
Town/City	Kingsford		
County	Dickinson	State	Michigan

Land-Surface Elevation and Datum 1121.79 feet MSL
[X] Surveyed
[ ] Estimated

Installation Date(s)	5/16/97 to 5/17/97
Drilling Method	Rotasonic
Drilling Contractor	Boart Longyear
Drilling Fluid	Water

Development Technique(s) and Date(s).
Pumping with Rediflow submersible pump set against well screen.
Pumped in 5 steps from 0.57 to 3.34 gpm.

Water Removed During Development	Approx.140	gallons
Static Depth to Water	82.07 on 5/29/97	feet below M.P.
Pumping Depth to Water	108.27 at 3.34 gpm	feet below M.P.
Pump Duration	0.5 (/step) hours	(2.5 hrs total test)
Date	5/29/1997	
Specific Capacity	0.127 (max)	gpm/ft
Specific Capacity	0.118 (averaged)	gpm/ft
Well Purpose	Monitoring groundwater levels and water quality.	

Remarks Note, specific capacity of 0.118 determined from averaging the specific capacities of 5 x 20 min steps.
Groundwater sample taken for analysis on 6/24/97.

Prepared by R. Flynn/J. McCallion

* Depth Below Land Surface

Project	WI0637.001	Well	GM-2A
Town/City	Kingsford		
County	Dickinson	State	Michigan

Land-Surface Elevation and Datum 1121.3 feet MSL
[X] Surveyed
[ ] Estimated

Installation Date(s)	5/7/97
Drilling Method	Rotasonic
Drilling Contractor	Boart Longyear
Drilling Fluid	Water

Development Technique(s) and Date(s).
Baildown

Water Removed During Development		7	gallons
Static Depth to Water	49.56 on 5/28/97		feet below M.P.
Pumping Depth to Water			feet below M.P.
Pump Duration	hours		
Yield	gpm	Date	5/29/1997
Specific Capacity		gpm/ft	

Well Purpose: Monitoring groundwater levels and groundwater quality.

Remarks: Purged 7 gallons from well.
Groundwater sample taken for analysis on 7/2/97.

Prepared by: D. Hegrenes/R. Flynn

* Depth Below Land Surface

Project	WI0637.001	Well	GM-2B
Town/City	Kingsford		
County	Dickinson	State	Michigan

Land-Surface Elevation and Datum 1121.33 feet MSL
[X] Surveyed
[ ] Estimated

Installation Date(s)	5/6/97 to 5/7/97
Drilling Method	Rotasonic
Drilling Contractor	Boart Longyear
Drilling Fluid	Water

Development Technique(s) and Date(s).
Pumping with Rediflow submersible pump set against well screen.
Pumped in 3 steps from 1.2 - 4 gpm

Water Removed During Development	Approx. 400		gallons
Static Depth to Water		73.33 on 5/28/97	feet below M.P.
Pumping Depth to Water		91.47 to 1.3 gpm	feet below M.P.
Pump Duration	3	hours	
Date	5/28/1997		
Specific Capacity	0.073	gpm/ft	
Well Purpose	Monitoring groundwater levels and groundwater quality.		

Remarks Note, specific capacity of 0.073 determined from averaging the specific capacites at two different pumping rates.
Groundwater sample taken for analysis on 6/26/97.

Prepared by R. Flynn/J. McCallion

Drilling Method Rotasonic

Drilling Contractor Boart Longyear

Drilling Fluid

Development Technique(s) and Date(s)

Baildown

Fluid Loss During Drilling gallons

Water Removed During Development gallons

Static Depth to Water 82.97 on 9/2/98 feet below M.P.

Pumping Depth to Water feet below M.P.

Pumping Duration hours

Yield gpm Date 9/2/1998

Specific Capacity gpm/ft

Well Purpose Monitoring groundwater levels and water quality.

Remarks Well was bailed dry. 3.5 gallons of water previously bailed on 8/20/98 for treatability water sampling.

Prepared by John Keller

Development Technique(s) and Date(s)

Disposable PE bailer

Fluid Loss During Drilling gallons

Water Removed During Development approximately 16 gallons

Static Depth to Water 48.82 feet below M.P.

Pumping Depth to Water feet below M.P.

Pumping Duration hours

Yield gpm Date 7/25/2000

Specific Capacity gpm/ft

Well Purpose Monitoring groundwater levels and water quality

Remarks Water color initially a dark silty brown, as developed, water changed to a light grey with no odor.

Prepared by John Keller/Lauren Barker

Project Ford/Kingsford WI001095.0002 Well GMSG-461

Town/City Kingsford - 2000 N. Plye Drive, Woodland School

County Dickinson

Permit No. NA

Land-Surface Elevation

1127.90 feet ☒ surveyed ☐ estimated

Datum Mean sea level

Installation Date(s) 7/7/05

Drilling Method Hand Auger

Drilling Contractor ARCADIS

Drilling Fluid None

Development Technique(s) and Date(s)

NA

Fluid Loss During Drilling -- gallons

Water Removed During Development -- gallons

Static Depth to Water -- feet below M.P.

Pumping Depth to Water -- feet below M.P.

Pumping Duration _____ hours

Yield -- gpm

Specific Capacity -- gpm/ft Date --

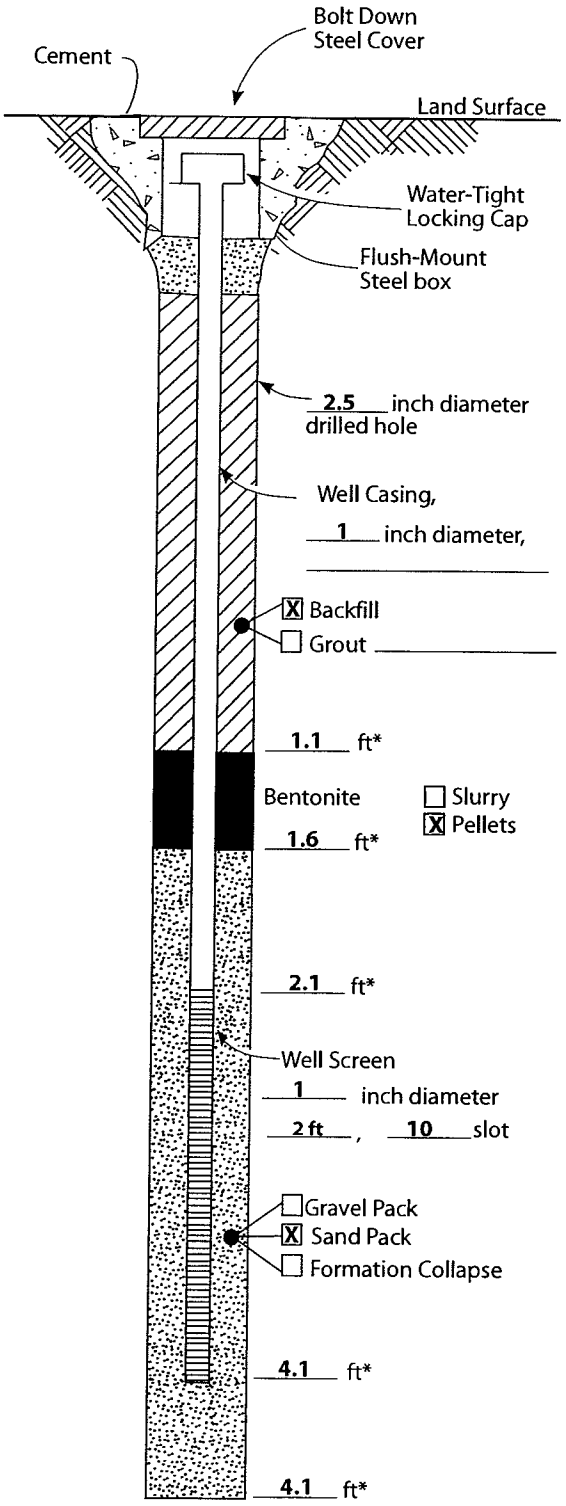
Specific Capacity -- gpm/ft

Well Purpose Commercial soil vapor probe

Remarks

Prepared by RJG/GJM

Well Construction Log
(Flush Mounted Well)



Measuring Point is Top of Well Casing Unless Otherwise Noted

*Depth Below Land Surface

Fluid Loss During Drilling _____ gallons

Water Removed During Development _____ gallons

Static Depth to Water _____ feet below M.P.

Pumping Depth to Water _____ feet below M.P.

Pumping Duration _____ hours

Yield _____ gpm

Specific Capacity _____ gpm/ft Date _____

Specific Capacity _____ gpm/ft

Well Purpose **Observation well**

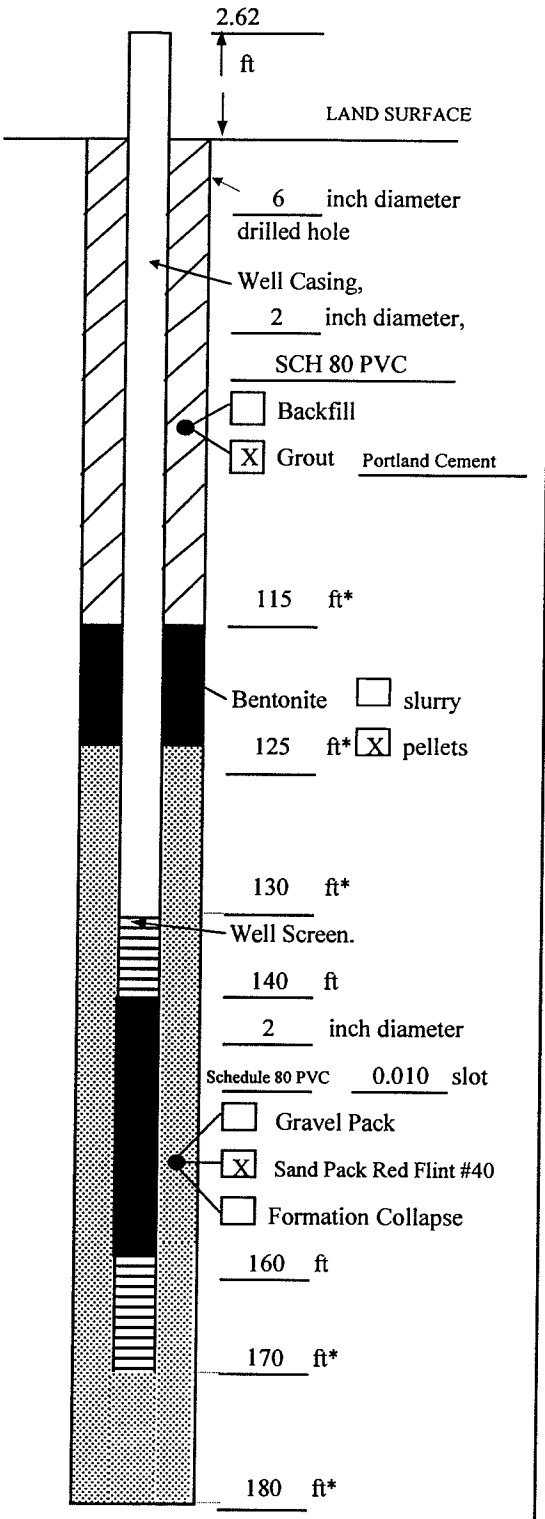
Remarks **Total depth drilled = 190 feet formation collapsed up to approximately 150 feet before well construction.**

Prepared by **Paul Lenaker**

ford/wi0637/2004/graphics/logs/gmpz8.ai

ARCADIS

WELL CONSTRUCTION LOG
(UNCONSOLIDATED)



Measuring Point is
Top of Well Casing
Unless Otherwise Noted.

* Depth Below Land Surface (bls)

Project Ford/Kingsford WI001025.0033 Probe GMPZ-9

Town/City Kingsford

County Dickinson State Michigan

Land-Surface Elevation 1048.31 feet
[X] Surveyed
[ ] Estimated

Installation Date(s) 10/14/03

Drilling Method Rotosonic

Drilling Contractor Boart Longyear

Drilling Fluid Water

Development Technique(s) and Date(s)

Fluid Loss During Drilling _____ gallons

Water Removed During Development _____ gallons

Static Depth to Water _____ feet below M.P.

Pumping Depth to Water _____ feet below M.P.

Pumping Duration _____ hours

Yield _____ gpm Date _____

Specific Capacity _____ gpm/ft

Well Purpose Observation well

Remarks Well screened in 2 discrete intervals from 120-130' and from 160-170'.

Prepared by Paul Lenaker

Appendix D

Specific Capacity Test Calculations

Because we care
100% recycled paper produced by wind power energy

Appendix D

Specific Capacity Test Calculations

Specific capacity tests were performed in conjunction with the well development activities for select monitoring wells (Table E-1). The monitoring wells were pumped using a Grundfos 2-inch submersible pump and water level measurements were taken with a Solinst water level meter. The pumping rate, in units of gallons per minute, was determined by estimating the time it took to fill up a one-gallon plastic jug. The duration of the tests depended on the amount of fine material that had collected in the well and ranged from just over an hour to five and a half hours (See Table E-2). The wells were pumped until ten well volumes were purged or until water quality was acceptable, and then the wells were allowed to recharge until the water level recovered to approximately 90% of the original static water level (See Table E-3).

Specific capacity tests were also performed in conjunction with aquifer pump tests performed on two extraction wells, GMEW-1 and GMEW-2, in August of 2000. The pump tests were performed with a Grundfos 3-inch submersible pump. Water level measurements were recorded using pressure transducers approximately 1-2 feet above the bottom of the well and all measurements were downloaded to hermit dataloggers. A simultaneous flow meter was installed a few feet away from the extraction well to measure the flow rate and a cumulative meter was installed to check the accuracy of the readings. These aquifer pump tests lasted six hours and were composed of three steps with incremental increases in pumping rates for each step.

The purpose of the specific capacity tests was to determine the hydraulic properties of the deposits beneath the study area. Well responses to pumping were analyzed to estimate the specific capacity of the monitoring wells and the resultant transmissivity and hydraulic conductivity of the deposits surrounding the well screen.

Transmissivity can be calculated using specific capacity data from a fully penetrating well by applying the Theis equation. The Theis equation is written as follows:

$$s = \frac{Q}{4\pi T} W(u)$$

$$u = \frac{r^2 S}{4Tt}$$

where,

s = drawdown of a fully penetrating well, in feet,
Q = discharge rate, in ft^3/day,
T = transmissivity, in ft^2/day,
$W(u)$ = Theis well function (an exponential integral),

penetrating. Partial-penetration curves from page 250 of *Groundwater and Wells* (Driscoll, 1986) based on the Kozeny (1933) correction equation were used for this purpose.

For each well, the percentage of the aquifer thickness that was penetrated by the well screen was computed and, using this parameter, the partial-penetration curves were used to determine a partial-penetration factor, which is the ratio of the observed to theoretical specific capacity. Then, the observed specific capacity was divided by the partial-penetration factor to obtain the theoretical specific capacity of a fully penetrating well.

Table E-1 shows the input parameters used and the results of the calculations for the wells that were analyzed. For each well, the last (highest) pumping rate was used in the calculations. The duration of pumping at that particular rate was used as the pumping time in the equation. Thus, the previous pumping at lower rates prior to the final rate was ignored in the transmissivity calculations. A borehole radius of 0.25-feet was used in the partial penetration correction and in the calculations. An assumed storage coefficient of 0.0005 was used in the calculation, typical for confined conditions such as those observed at the site.

The aquifer thickness and screen length values shown in Table E-1 were determined from logs of the wells. These parameters were used to determine the partial-penetration correction factors and corrected specific capacity values shown in the table. Then the Cooper-Jacob equation was solved using an iterative procedure to produce the transmissivity values shown. Finally, the computed transmissivity was divided by the formation thickness to determine a representative hydraulic conductivity value for each zone.

Footnotes on Page 3.

Table D-1. Results from Specific Capacity Tests and Calculated Hydraulic Conductivities, Ford/KingsfordSite, Kingsford, Michigan.

Unit 3

No wells completed in this unit.

Unit 1	Unit 1 relates to the unit of the 3D geologic model characteristic of sand and gravel.
Unit 2	Unit 2 relates to the unit of the 3D geologic model characteristic of very fine sand to sandy silt.
Unit 3	Unit 3 relates to the unit of the 3D geologic model characteristic of silt and clay.
Note:	Volume and Discharge measured at end of step with highest discharge rate.
cm/sec	Centimeters per second.
FT BTOC	Feet below top of casing.
Ft^2/Day	Square feet per day.
GPM	Gallons per minute.
GPM/ft	Gallons per minute per foot of drawdown.

INTRODUCTION

During the period of July 20 through November 2, 1997, electromagnetic, ground penetrating radar (GPR), and seismic reflection surveys were conducted at the Easton Estates site located in Kingsford, Michigan. The GPR survey was intended to characterize the unsaturated overburden while the seismic reflection survey was expected to characterize the depth to bedrock. An electromagnetic (EM31) survey, conducted in July, was used to evaluate if the surface conductivities were appropriate for conducting a GPR survey. As part of the investigation a boring program was established. To supplement the boring program, a non-intrusive geophysical program was developed to assist in characterizing the overburden and depth to bedrock.

INSTRUMENTATION

The electromagnetic survey implemented Geonics' EM31 terrain conductivity system. The EM31 system was operated in both the vertical and horizontal dipole modes. Apparent conductivity and inphase measurements were electronically stored on an attached data logger. The GPR survey implemented a pulse EKKO IV ground penetrating radar system manufactured by Sensors & Software, Inc. Acquisition, field output, and data storage are achieved through the use of a laptop computer. Antennas ranged from 50 to 200 MHz.

The seismic reflection survey utilized a Geometerics 48 channel instantaneous floating point (IFP) seismograph, a Bison Elastic Wave Generator (EWG) pulled by a Ford 1710 diesel tractor, Mark 40 Hz geophones connected to cables with swamp connectors and 10 foot take-out spacings. The reflection data is processed on Eavesdropper software licensed by the Kansas Geological Survey (KGS).

METHODOLOGY

Ground control was established by tying station locations along a geophysical line to cultural features. These features include streets, places (e.g., the park, wastewater treatment facility, and wells), and geographic descriptions (e.g., bottom of hill, middle of slope, top of hill, on grass, on asphalt). A base map for the site is presented in **Figure 1: Easton Estates Site--Geophysical Investigation.**

The preliminary EM31 data were acquired from the northwest end of Test 1, along Grant from Sagoloa to approximately 200 feet north of Breitung, and along the north side of Breitung from approximately Grant to LoDAL Park Road. Figure 1 shows the placement of the GPR and seismic reflection lines. With the exception of the seismic reflection lines, GPR data was acquired along each of the dark black lines. The seismic reflection lines are labeled Menominee River Line, East-West Line, Balsam 1 Line, and Balsam 2 Line.

The GPR surveys digitally recorded data along transect lines and with parameters consistent with the manufactures recommendations. Since data was collected with several different nominal frequencies the distance between stations varied. Though the targets are spatially large a relatively small spacing between stations is implemented in an effort to avoid spatial aliasing. An approximately 3 to 4 foot step size (station spacing), a 1000 volt pulser voltage, a 128 stack record, and a reflection survey mode is utilized for each transect line. The nominal frequency varied from 50 to 200 Megahertz. Spacing between coils for the 50 Megahertz acquisition is approximately 7.5 feet, for the 100 Megahertz acquisition is approximately 3.75 to 4 feet, and for the 200 Megahertz acquisition is

approximately 2 feet. Each trace consists of a 500 nanoseconds total time window. This record length is theoretically long enough to obtain events in excess of approximately 100 feet deep, assuming an average velocity 0.492 feet per nanosecond. However, reflections from depths much in excess of 40 feet were not anticipated. The survey parameters were selected on the basis of the guidelines provided by the manufacture and Annan and Cosway (1992).

The geometry and recording parameters for the seismic reflection survey were based on a comparison of boring logs and walkouts from two test sites. A walkout consists of setting out a geophone array and acquiring data with shot points located at the first geophone and at distances from the first geophone in increments equal to the length of the geophone array. The end result, after the successive records are joined together, is a large panel showing the relationship of seismic events in time verses distance away or offset from the source. The first walkout was conducted near boring GMSB-1 and the second walkout was conducted near boring GM-4. At GMSB-1, bedrock is expected at a depth of approximately 290 feet with the upper 50 feet unsaturated. In contrast, the bedrock at GM-4 is shallow and expected at a depth of approximately 120 feet with the upper 60 feet unsaturated. At the mobile processing center, models were generated from the results of the boring logs and from a range of interval velocities. While coherent events were observed in both walkouts and correlated well with the models, it was apparent that a continuous reflection across an entire set of 24 traces was unlikely for lines with very shallow bedrock and very deep bedrock. In other words, the geometry ideal for recording a reflection from shallow bedrock would not be ideal for the deepest bedrock. Hence, the selected geometry attempted to maximize the recording of reflected energy from moderate depths and minimized the number of traces not recording reflected energy from very shallow and very deep bedrock. In addition, the spacing of the geophones attempted to

maximize the available recordable normal moveout, which maximizes the stacking or signal to noise capabilities of the common depth point method. On the basis of discussion about the walkouts in the field with others, an end on 12 fold common depth point (CDP) survey was designed with a minimum offset of 140 feet and a geophone spacing of 7 feet. Five hundred millisecond records were recorded at a sample rate of .5 milliseconds. The field filters were set fairly wide with a band pass of 25 to 250 Hz and a 60Hz notch filter. Each trace consists of a single geophone, often with stacks ranging from 4 to 8 shots. Results were not significantly enhanced by stacking more than 8 shots. Each shot was generated by the EWG with shot stations spaced 7 feet apart. After the seismic data was acquired it was reformatted for processing with the KGS software. A spectral analysis was evaluated. Data was then filtered with a bandpass of 25-150 Megahertz, edited, muted, CDP sorted, and corrected for surface statics. A velocity scan was then completed on the sorted and corrected data. From the velocity scan, a set of stacking velocities were chosen to process the results. A filtered and automatic gain controlled (AGC) CDP stacked section was generated from the selected stacking velocities. The four stacked sections are created from a total of approximately 2625 field records or approximately 5350 CDP locations.

Geophysical Assumptions

In a geophysical site characterization as the one performed at the Easton Estates site, it was understood from the beginning that no one method would clearly answer all the questions about the site. If certain assumptions were made and held true, each method of investigation should yield desirable results. On the basis of the EM31 results, there was a high level of confidence that the GPR would penetrate deep enough to characterize the unsaturated overburden, assuming minimal cultural interference (i.e. buildings, fencing,

and demolition debris) and attenuation. With the exception of areas where the meter readings appeared to be artificially elevated by the presence of nearby cultural interference, the apparent soil conductivities were typically below 3 millimhos per meter. As a rough estimate, the depth of penetration is approximately equal to 35 divided by the soil conductivity in millimhos per meter. Hence, soil conductivities of 2 to 3 millimhos per meter are expected to yield depths of penetration of approximately 11.5 to 17.5 meters or 37 to 57 feet. Once the depth of penetration is established, it is assumed that a detectable dielectric and/or conductivity contrast exists between units of interest. These detectable contrasts in electrical properties reflect the electromagnetic energy. Hence, these units must be thick enough to produce an interpretable reflection. The most rigorous assumptions are that the transmitted electromagnetic energy propagated at a relatively constant velocity and was able to reach the receiver after being reflected off the desired target. In general, reflected energy is increasingly attenuated and the velocity decreased by an increase in the electrical conductivities. The depth of an interpreted event is then calculated from the measured time and an assumed velocity.

The assumptions made for the GPR survey closely parallel assumptions made for the seismic reflection survey. First of all, it is assumed that coherent energy is transmitted down to the bedrock and returned to a geophone, along a reasonable geometric path. Where reflections in a GPR survey are generated by variations in the electrical properties, reflections in a seismic survey are generated by variations in the mechanical properties. In both cases, the end result is measuring the time for a wave to propagate to a reflector at depth and return to the surface. The depth of the interpreted event is then calculated from the measured time and an assumed velocity.

PRESENTATION OF RESULTS

On July 20, a limited EM31 survey was conducted to determine if the soil conductivities were conducive for a GPR survey. As discussed in the Geophysical Assumption, the apparent conductivities are generally below 3 millimhos per meter. These relatively low conductivity values suggested that a GPR survey should yield desirable results. Starting on August 6, a series of tests were conducted with 50 and 100 Megahertz antennas. After the first session, it appeared the 50 Megahertz results lacked the detail provided by the 100 Megahertz antenna. Typically, the depth of penetration for the 50 Megahertz results would be greater; however, the 100 Megahertz response often yielded reflections from travel times in excess of 160 nanoseconds. Thus during the second session, starting October 29, 1997, a series of GPR lines with 100, and 200 Megahertz antennas were conducted. The 200 Megahertz antenna was tested to determine if greater detail could be achieved without the loss of penetration. The results of these surveys are included in **Appendix A: Easton Estates Site -- GPR Records**. Continuous records were supplied to ARCADIS Geraghty & Miller for their use. While the stations across the top of the plot approximate distance, the station setting was reset to 0, if a new file was opened to continue the line. The plots are attached in sequential order.

During the period from September 15 through September 2, four seismic reflection lines were acquired. The results of the reflection survey are included in **Appendix B: Easton Estates Site -- Seismic Reflection Lines.** As the velocity of the unconsolidated material varies laterally across a line, the position of a reflection may also vary.

Ground Penetrating Radar

Two areas were designated for conducting test lines, as shown in Figure 1. The 50, 100, and 200 Megahertz GPR lines, conducted at Test 1, started at the west edge of Garfield, followed the entrance into the staging area, and ended on the west side of the pit. The 50 and 100 Megahertz GPR lines conducted at Test 2 started on the west edge of Garfield, followed the top of the north edge of the pit past well GM1, and then headed north on a gravel road. These lines ended at the southern edge of Breitung. These two areas were chosen because wells were placed along the lines and little cultural interference was expected.

In viewing the GPR figures, or other radar results contained in this report, it should be noted that the depth scale is a relative scale. Transit time of the radar pulse is the accurately measured quantity and conversion to depth requires an assumption of the electromagnetic propagation velocity. Propagation velocities were not measured. The velocity of 0.492 feet per nanosecond is an estimate.

As expected, an increase in resolution is observed as the antenna frequencies increase. In addition, the amount of the reflected energy decreases as the antenna frequencies increase, which is also expected. A comparison of the results for lines 5KGMT1/TEST LINE1, 1KGMT1/TEST LINE1, and 2KGMT1/TEST 1 all indicate a strong coherent reflection at approximately 90 nanoseconds at the start of the line. This event is clearly followed to approximately the middle of each line, where the drop in elevation is seen at the top of the record. The reflection appears at approximately 60 nanoseconds. From this location towards the west the reflection becomes more difficult to follow. However, it is interpreted to dip towards the west and eventually level off at approximately 80

nanoseconds. Unlike the results for 2KGMT1/TEST 1, the lower frequency 5KGMT1/TEST LINE 1 and 1KGMT1/TEST LINE1 results yielded reflected energy after 125 nanoseconds. The source of the deeper reflected energy from approximately 150 nanoseconds is unknown.

A comparison of the results for 5KGMT2/TEST LINE 2 and 1KGMT2/ TEST LINE 2, yielded nearly identical results. In both cases, returned energy is recorded throughout the record. 1KGMT2/TEST LINE 2 starts with a reflection at approximately 150 nanoseconds near station 0, continues across the line and ends up at approximately 100 nanoseconds near station 1000. This event is difficult to observe, but even more difficult to follow on line 5KGMT2/TEST LINE2.

While the 50 Megahertz antenna yielded greater depths of penetration, the 200 Megahertz antenna yielded the greatest resolution. At the time of the survey it was agreed, the 100 Megahertz provided the best compromise between penetration and resolution. This is supported by data collected along Beech. The 200 Megahertz record, BEECH 200 Megahertz, provides good definition, when energy is returned. However, the continuity of the deeper reflector north of Emmet is clearly better in the 100 Megahertz record, BEECH. On the basis of these comparisons, the majority of the GPR data collected during the second session was acquired with the 100 Megahertz antenna. A list of the acquired GPR lines, which includes the antenna frequency, are presented at the beginning of Appendix A.

The quality of the GPR data is easily tested by two simple observations. First of all, the data should be repeatable. And secondly, lines conducted perpendicular to each other should yield the same results at their intersection. This intersection of lines is called a tie

point. A comparison of all the GPR records at the tie points, yielded a very high correspondence. Major discrepancies were not apparent. Observed minor variations were often explained by cultural interference, which was associated with an intersection of two streets. In addition to the repeatability demonstrated in the test results, portions of 100 Megahertz data collected along Breen intentionally overlapped. Though the data collected along 1KGMC/BREEN was acquired from west to east and the data collected along BREEN was acquired from east to west, the area between Beech and the alley west of Beech was repeated. Along 1KGMC/BREEN station 2075 is near the alley and station 2225 ends at Beech. In contrast, along BREEN station 1690 is near Beech and station 1870 ends at the alley. The results at these two locations are mirrored images and correlate very well. The portion of record along 1KGMC/BREEN from 1925 to 2070 correlates well with cultural interference generated by utilities. Since no other area along the street was available to acquire data without interference, the GPR line was conducted down the center of the street up to station 2020. From station 2020 to 2070 the line systematically veered off towards the south, near GM2. This test provided a clear indication of the response from a utility (water main) at this site and an estimate of the distance from a buried utility that interference would be encountered.

The interpretation of ground penetrating radar is somewhat subjective and unique interpretations are generally not possible. There are fairly consistent events seen across many of the GPR lines. The 100 Megahertz data collected along line BEECH is a fairly good example of the results acquired. Often the region south of the "hill," seen between stations 0 and 450, yielded either poorly defined reflections or reflections shallower in time, then above the hill. The reflections below the hill are typically less than 100 nanoseconds. The deepest basal reflection observed north of the hill, between stations 650 and 1985, often ranged between 100 and 150 nanoseconds. In many areas north of the hill,

one or more shallower reflections may be observed. Many of the intersections experienced a loss of record while crossing an intersection. A good example of this is observed at station 1325, the center of Breen.

Seismic Reflection Survey

After the walkouts were completed, data were collected starting at the north end of Balsam. The first shot station is labeled 101 and the end of the line is labeled 635, Figure 1. Because of traffic, data could not be collected across Breitung. Hence, the southern portion of Balsam was shot as a separate line. The line started at station 2101 and ended near station 2400. After Balsam 1 and Balsam 2 Lines were completed, the Menominee River Line was acquired from the northwest, station 1101, towards the southeast and ended near station 2400. The East-West Line was the last line shot. It started at Westwood, station 1101, and ended short of Balsam, station 1470. The stations discussed so far represent stations marked in the field for shooting and recording the seismic data. Reflection data that is reduced to a stack is annotated with CDP labels across the top of the section, 1/2 of a CDP station number represents the field station number from where the reflected event is projected to occur along the line. Laterally distances are measured from the beginning of a line. Depths to ground level, saturation, or bedrock, as provided by the test borings, have been converted to depths from a reference datum to eliminate the effects of surface relief. For Balsam 1 Line, Balsam 2 Line, and the East-West Line depths are measured from a datum of 1150 feet. For the Menominee River Line depths are measured from a datum of 1065 feet. The thickness of the unsaturated zone may play a crucial role in determining the depth to bedrock. These data were provided by ARCADIS Geraghty & Miller.

INTRODUCTION

During the period of July 20 through November 2, 1997, electromagnetic, ground penetrating radar (GPR), and seismic reflection surveys were conducted at the Easton Estates site located in Kingsford, Michigan. The GPR survey was intended to characterize the unsaturated overburden while the seismic reflection survey was expected to characterize the depth to bedrock. An electromagnetic (EM31) survey, conducted in July, was used to evaluate if the surface conductivities were appropriate for conducting a GPR survey. As part of the investigation a boring program was established. To supplement the boring program, a non-intrusive geophysical program was developed to assist in characterizing the overburden and depth to bedrock.

INSTRUMENTATION

The electromagnetic survey implemented Geonics' EM31 terrain conductivity system. The EM31 system was operated in both the vertical and horizontal dipole modes. Apparent conductivity and inphase measurements were electronically stored on an attached data logger. The GPR survey implemented a pulse EKKO IV ground penetrating radar system manufactured by Sensors & Software, Inc. Acquisition, field output, and data storage are achieved through the use of a laptop computer. Antennas ranged from 50 to 200 MHz.

The seismic reflection survey utilized a Geometerics 48 channel instantaneous floating point (IFP) seismograph, a Bison Elastic Wave Generator (EWG) pulled by a Ford 1710 diesel tractor, Mark 40 Hz geophones connected to cables with swamp connectors and 10 foot take-out spacings. The reflection data is processed on Eavesdropper software licensed by the Kansas Geological Survey (KGS).

METHODOLOGY

Ground control was established by tying station locations along a geophysical line to cultural features. These features include streets, places (e.g., the park, wastewater treatment facility, and wells), and geographic descriptions (e.g., bottom of hill, middle of slope, top of hill, on grass, on asphalt). A base map for the site is presented in **Figure 1: Easton Estates Site--Geophysical Investigation.**

The preliminary EM31 data were acquired from the northwest end of Test 1, along Grant from Sagoloa to approximately 200 feet north of Breitung, and along the north side of Breitung from approximately Grant to LoDAL Park Road. Figure 1 shows the placement of the GPR and seismic reflection lines. With the exception of the seismic reflection lines, GPR data was acquired along each of the dark black lines. The seismic reflection lines are labeled Menominee River Line, East-West Line, Balsam 1 Line, and Balsam 2 Line.

The GPR surveys digitally recorded data along transect lines and with parameters consistent with the manufactures recommendations. Since data was collected with several different nominal frequencies the distance between stations varied. Though the targets are spatially large a relatively small spacing between stations is implemented in an effort to avoid spatial aliasing. An approximately 3 to 4 foot step size (station spacing), a 1000 volt pulser voltage, a 128 stack record, and a reflection survey mode is utilized for each transect line. The nominal frequency varied from 50 to 200 Megahertz. Spacing between coils for the 50 Megahertz acquisition is approximately 7.5 feet, for the 100 Megahertz acquisition is approximately 3.75 to 4 feet, and for the 200 Megahertz acquisition is

approximately 2 feet. Each trace consists of a 500 nanoseconds total time window. This record length is theoretically long enough to obtain events in excess of approximately 100 feet deep, assuming an average velocity 0.492 feet per nanosecond. However, reflections from depths much in excess of 40 feet were not anticipated. The survey parameters were selected on the basis of the guidelines provided by the manufacture and Annan and Cosway (1992).

The geometry and recording parameters for the seismic reflection survey were based on a comparison of boring logs and walkouts from two test sites. A walkout consists of setting out a geophone array and acquiring data with shot points located at the first geophone and at distances from the first geophone in increments equal to the length of the geophone array. The end result, after the successive records are joined together, is a large panel showing the relationship of seismic events in time verses distance away or offset from the source. The first walkout was conducted near boring GMSB-1 and the second walkout was conducted near boring GM-4. At GMSB-1, bedrock is expected at a depth of approximately 290 feet with the upper 50 feet unsaturated. In contrast, the bedrock at GM-4 is shallow and expected at a depth of approximately 120 feet with the upper 60 feet unsaturated. At the mobile processing center, models were generated from the results of the boring logs and from a range of interval velocities. While coherent events were observed in both walkouts and correlated well with the models, it was apparent that a continuous reflection across an entire set of 24 traces was unlikely for lines with very shallow bedrock and very deep bedrock. In other words, the geometry ideal for recording a reflection from shallow bedrock would not be ideal for the deepest bedrock. Hence, the selected geometry attempted to maximize the recording of reflected energy from moderate depths and minimized the number of traces not recording reflected energy from very shallow and very deep bedrock. In addition, the spacing of the geophones attempted to

maximize the available recordable normal moveout, which maximizes the stacking or signal to noise capabilities of the common depth point method. On the basis of discussion about the walkouts in the field with others, an end on 12 fold common depth point (CDP) survey was designed with a minimum offset of 140 feet and a geophone spacing of 7 feet. Five hundred millisecond records were recorded at a sample rate of .5 milliseconds. The field filters were set fairly wide with a band pass of 25 to 250 Hz and a 60Hz notch filter. Each trace consists of a single geophone, often with stacks ranging from 4 to 8 shots. Results were not significantly enhanced by stacking more than 8 shots. Each shot was generated by the EWG with shot stations spaced 7 feet apart. After the seismic data was acquired it was reformatted for processing with the KGS software. A spectral analysis was evaluated. Data was then filtered with a bandpass of 25-150 Megahertz, edited, muted, CDP sorted, and corrected for surface statics. A velocity scan was then completed on the sorted and corrected data. From the velocity scan, a set of stacking velocities were chosen to process the results. A filtered and automatic gain controlled (AGC) CDP stacked section was generated from the selected stacking velocities. The four stacked sections are created from a total of approximately 2625 field records or approximately 5350 CDP locations.

Geophysical Assumptions

In a geophysical site characterization as the one performed at the Easton Estates site, it was understood from the beginning that no one method would clearly answer all the questions about the site. If certain assumptions were made and held true, each method of investigation should yield desirable results. On the basis of the EM31 results, there was a high level of confidence that the GPR would penetrate deep enough to characterize the unsaturated overburden, assuming minimal cultural interference (i.e. buildings, fencing,

and demolition debris) and attenuation. With the exception of areas where the meter readings appeared to be artificially elevated by the presence of nearby cultural interference, the apparent soil conductivities were typically below 3 millimhos per meter. As a rough estimate, the depth of penetration is approximately equal to 35 divided by the soil conductivity in millimhos per meter. Hence, soil conductivities of 2 to 3 millimhos per meter are expected to yield depths of penetration of approximately 11.5 to 17.5 meters or 37 to 57 feet. Once the depth of penetration is established, it is assumed that a detectable dielectric and/or conductivity contrast exists between units of interest. These detectable contrasts in electrical properties reflect the electromagnetic energy. Hence, these units must be thick enough to produce an interpretable reflection. The most rigorous assumptions are that the transmitted electromagnetic energy propagated at a relatively constant velocity and was able to reach the receiver after being reflected off the desired target. In general, reflected energy is increasingly attenuated and the velocity decreased by an increase in the electrical conductivities. The depth of an interpreted event is then calculated from the measured time and an assumed velocity.

The assumptions made for the GPR survey closely parallel assumptions made for the seismic reflection survey. First of all, it is assumed that coherent energy is transmitted down to the bedrock and returned to a geophone, along a reasonable geometric path. Where reflections in a GPR survey are generated by variations in the electrical properties, reflections in a seismic survey are generated by variations in the mechanical properties. In both cases, the end result is measuring the time for a wave to propagate to a reflector at depth and return to the surface. The depth of the interpreted event is then calculated from the measured time and an assumed velocity.

PRESENTATION OF RESULTS

On July 20, a limited EM31 survey was conducted to determine if the soil conductivities were conducive for a GPR survey. As discussed in the Geophysical Assumption, the apparent conductivities are generally below 3 millimhos per meter. These relatively low conductivity values suggested that a GPR survey should yield desirable results. Starting on August 6, a series of tests were conducted with 50 and 100 Megahertz antennas. After the first session, it appeared the 50 Megahertz results lacked the detail provided by the 100 Megahertz antenna. Typically, the depth of penetration for the 50 Megahertz results would be greater; however, the 100 Megahertz response often yielded reflections from travel times in excess of 160 nanoseconds. Thus during the second session, starting October 29, 1997, a series of GPR lines with 100, and 200 Megahertz antennas were conducted. The 200 Megahertz antenna was tested to determine if greater detail could be achieved without the loss of penetration. The results of these surveys are included in **Appendix A: Easton Estates Site -- GPR Records**. Continuous records were supplied to ARCADIS Geraghty & Miller for their use. While the stations across the top of the plot approximate distance, the station setting was reset to 0, if a new file was opened to continue the line. The plots are attached in sequential order.

During the period from September 15 through September 2, four seismic reflection lines were acquired. The results of the reflection survey are included in **Appendix B: Easton Estates Site -- Seismic Reflection Lines.** As the velocity of the unconsolidated material varies laterally across a line, the position of a reflection may also vary.

Ground Penetrating Radar

Two areas were designated for conducting test lines, as shown in Figure 1. The 50, 100, and 200 Megahertz GPR lines, conducted at Test 1, started at the west edge of Garfield, followed the entrance into the staging area, and ended on the west side of the pit. The 50 and 100 Megahertz GPR lines conducted at Test 2 started on the west edge of Garfield, followed the top of the north edge of the pit past well GM1, and then headed north on a gravel road. These lines ended at the southern edge of Breitung. These two areas were chosen because wells were placed along the lines and little cultural interference was expected.

In viewing the GPR figures, or other radar results contained in this report, it should be noted that the depth scale is a relative scale. Transit time of the radar pulse is the accurately measured quantity and conversion to depth requires an assumption of the electromagnetic propagation velocity. Propagation velocities were not measured. The velocity of 0.492 feet per nanosecond is an estimate.

As expected, an increase in resolution is observed as the antenna frequencies increase. In addition, the amount of the reflected energy decreases as the antenna frequencies increase, which is also expected. A comparison of the results for lines 5KGMT1/TEST LINE1, 1KGMT1/TEST LINE1, and 2KGMT1/TEST 1 all indicate a strong coherent reflection at approximately 90 nanoseconds at the start of the line. This event is clearly followed to approximately the middle of each line, where the drop in elevation is seen at the top of the record. The reflection appears at approximately 60 nanoseconds. From this location towards the west the reflection becomes more difficult to follow. However, it is interpreted to dip towards the west and eventually level off at approximately 80

nanoseconds. Unlike the results for 2KGMT1/TEST 1, the lower frequency 5KGMT1/TEST LINE 1 and 1KGMT1/TEST LINE1 results yielded reflected energy after 125 nanoseconds. The source of the deeper reflected energy from approximately 150 nanoseconds is unknown.

A comparison of the results for 5KGMT2/TEST LINE 2 and 1KGMT2/ TEST LINE 2, yielded nearly identical results. In both cases, returned energy is recorded throughout the record. 1KGMT2/TEST LINE 2 starts with a reflection at approximately 150 nanoseconds near station 0, continues across the line and ends up at approximately 100 nanoseconds near station 1000. This event is difficult to observe, but even more difficult to follow on line 5KGMT2/TEST LINE2.

While the 50 Megahertz antenna yielded greater depths of penetration, the 200 Megahertz antenna yielded the greatest resolution. At the time of the survey it was agreed, the 100 Megahertz provided the best compromise between penetration and resolution. This is supported by data collected along Beech. The 200 Megahertz record, BEECH 200 Megahertz, provides good definition, when energy is returned. However, the continuity of the deeper reflector north of Emmet is clearly better in the 100 Megahertz record, BEECH. On the basis of these comparisons, the majority of the GPR data collected during the second session was acquired with the 100 Megahertz antenna. A list of the acquired GPR lines, which includes the antenna frequency, are presented at the beginning of Appendix A.

The quality of the GPR data is easily tested by two simple observations. First of all, the data should be repeatable. And secondly, lines conducted perpendicular to each other should yield the same results at their intersection. This intersection of lines is called a tie

point. A comparison of all the GPR records at the tie points, yielded a very high correspondence. Major discrepancies were not apparent. Observed minor variations were often explained by cultural interference, which was associated with an intersection of two streets. In addition to the repeatability demonstrated in the test results, portions of 100 Megahertz data collected along Breen intentionally overlapped. Though the data collected along 1KGMC/BREEN was acquired from west to east and the data collected along BREEN was acquired from east to west, the area between Beech and the alley west of Beech was repeated. Along 1KGMC/BREEN station 2075 is near the alley and station 2225 ends at Beech. In contrast, along BREEN station 1690 is near Beech and station 1870 ends at the alley. The results at these two locations are mirrored images and correlate very well. The portion of record along 1KGMC/BREEN from 1925 to 2070 correlates well with cultural interference generated by utilities. Since no other area along the street was available to acquire data without interference, the GPR line was conducted down the center of the street up to station 2020. From station 2020 to 2070 the line systematically veered off towards the south, near GM2. This test provided a clear indication of the response from a utility (water main) at this site and an estimate of the distance from a buried utility that interference would be encountered.

The interpretation of ground penetrating radar is somewhat subjective and unique interpretations are generally not possible. There are fairly consistent events seen across many of the GPR lines. The 100 Megahertz data collected along line BEECH is a fairly good example of the results acquired. Often the region south of the "hill," seen between stations 0 and 450, yielded either poorly defined reflections or reflections shallower in time, then above the hill. The reflections below the hill are typically less than 100 nanoseconds. The deepest basal reflection observed north of the hill, between stations 650 and 1985, often ranged between 100 and 150 nanoseconds. In many areas north of the hill,

one or more shallower reflections may be observed. Many of the intersections experienced a loss of record while crossing an intersection. A good example of this is observed at station 1325, the center of Breen.

Seismic Reflection Survey

After the walkouts were completed, data were collected starting at the north end of Balsam. The first shot station is labeled 101 and the end of the line is labeled 635, Figure 1. Because of traffic, data could not be collected across Breitung. Hence, the southern portion of Balsam was shot as a separate line. The line started at station 2101 and ended near station 2400. After Balsam 1 and Balsam 2 Lines were completed, the Menominee River Line was acquired from the northwest, station 1101, towards the southeast and ended near station 2400. The East-West Line was the last line shot. It started at Westwood, station 1101, and ended short of Balsam, station 1470. The stations discussed so far represent stations marked in the field for shooting and recording the seismic data. Reflection data that is reduced to a stack is annotated with CDP labels across the top of the section, 1/2 of a CDP station number represents the field station number from where the reflected event is projected to occur along the line. Laterally distances are measured from the beginning of a line. Depths to ground level, saturation, or bedrock, as provided by the test borings, have been converted to depths from a reference datum to eliminate the effects of surface relief. For Balsam 1 Line, Balsam 2 Line, and the East-West Line depths are measured from a datum of 1150 feet. For the Menominee River Line depths are measured from a datum of 1065 feet. The thickness of the unsaturated zone may play a crucial role in determining the depth to bedrock. These data were provided by ARCADIS Geraghty & Miller.

Appendix F

Laboratory Treatbility and Bacteria Enumeration Methods

Treatability Testing Materials and Methods

Soil for the treatability study was collected in a plexiglas liner from the bore hole identified as GMSB-1 from a depth of 307 feet to 317 feet. After being removed from the liner, the soil was placed in a 5 gallon bucket and covered with distilled water. The bucket was sealed and shipped for overnight delivery to ARCADIS Geraghty & Miller's treatability laboratory in Research Triangle Park, North Carolina. A groundwater sample was also collected from GMSB-1 at 317 feet. The groundwater sample was allowed to fill and overflow from the 1 gallon amber sample jugs prior to sealing the jugs with zero headspace. The groundwater was shipped for next day delivery to Geraghty & Miller's treatability laboratory. Once the soil and groundwater arrived at the laboratory, the soil was transferred from the 5 gallon bucket into sterile 1 gallon glass jars. This transfer was accomplished in a glove box under a nitrogen blanket. The soil in the glass jars was stored at 4° C until use. The groundwater was stored at 4 °C as received.

On June 12, 1997 the GMSB-1 soil was composited inside a nitrogen glove box in stainless steel bowls that had been disinfected with HPLC grade isopropanol (Fisher). The glove box was confirmed to be anaerobic using a BBL dry anaerobic indicator strip (Becton Dickinson Part No. 71051). Soil was transferred from one bowl to another using a large disinfected stainless steel spoon. After the transfer of each spoon of soil, mixing was initiated prior to the transfer of another spoon of soil. After thorough homogenization, eight soil microcosms were established. The microcosms were established in 2 liter pyrex laboratory bottles (Corning). The soil placed in each microcosm was weighed in plastic weigh boats that had been disinfected with HPLC grade isopropanol. Seven 400 gram aliquots of soil were required to fill each 2 liter bottle to the 1400 milliliter gradation. Two hundred milliliters of GMSB-1 groundwater was added to each microcosm.

The microcosms were sealed with the closure shown in Figure F-1. The closure consists of a screw-on HPLC bottle top (Dionex, Part No. 045896) with 2 three-way valves and one three-way large bore valve (Cole-Parmer, Part Nos. E-30600-02 and E-30600-10) mounted in it. One of the valves was coupled to a luer-lok manifold (Cole-Parmer, Part No. Z-06464-84 with polyethylene connecting tubing (Cole-Parmer, Part No. E-30600-63). A second valve had no connections. The large bore three-way valve was connected to 1/8" teflon tubing which ran through the stopper assembly and terminated below the water line within the microcosms (Figure F-1). The luer-lok manifold was connected to a nitrogen supply (99.999% N_2). Nitrogen was flushed through the headspace of each microcosm using the luer-lok manifold for 5 minutes. The nitrogen exited each microcosm through the unused valve which was adjusted to the open position. Following headspace flushing, all valves were closed.

The microcosms were incubated in the glove box at room temperature from June 12 to July 20, 1997. The head spaces of the microcosms were periodically pressure tested using an Omega pressure gauge which was connected directly to the unused valve on the top of each microcosm (Figure F-1). The pressure measurements in pounds per square inch (p.s.i.) were compared to a pressure curve generated by

injecting known amounts of air (1 to 30 cubic centimeters) into a 2 liter bottle with 1,600 ml of water in it and measuring the generated pressure. This comparison was periodically used to estimate the volume of gas generated by each microcosm. Periodically, headspace gas samples were removed from each microcosm and analyzed for methane using a Hewlett Packard 5890 gas chromatograph with a flame ionization detector. The column used for this testing was equivalent to Supelco's Part No. 1-0293 with 100/120 HayeSep D packing. The injection port and detector were operated at 250°C. The chromatographic analysis consisted of a two minute hold at 60°C followed by a 25°C/minute temperature increase for a final temperature of 180°C which was held for 3 minutes. Total run time was 11.40 minutes and the equilibration time was set for 0.10 minutes. Samples were collected from the microcosms within the glove box using 1 ml gas tight syringes (Supelco, Part No. 2-0720) fitted with push button valves (Supelco, Part No. 2-2285) which protected sample integrity between the glove box and the gas chromatograph. The push button valve accommodated a luer hub needle (Supelco Part No. 2-0757) which was used to inject the sample into the gas chromatograph. An air lock was used to access the microcosms without introducing atmospheric air into the glove box. Following analysis, all microcosm head spaces were flushed for 5 minutes with nitrogen gas using the luer-lok manifold. The results of methane headspace analysis can be found in Figure F-2. Figure F-2 shows cumulative methane production for the microcosms.

On July 20 the microcosms were amended. The treatments shown in Table F-1 were established. Hydrogen peroxide was added to the microcosm by diluting a 30% solution (Fisher Part No. FL-06-0793) and confirming the final concentration of hydrogen peroxide with a test kit (Hach Part No. 24491-00). Hydrogen peroxide was added in 10 ml of volume. Nitrate was added as an aqueous solution of calcium nitrate tetrahydrate (Aldrich Part No. 23712-4) in 10 ml sterile deionized water (DI). Sulfate was added as an aqueous solution of magnesium sulfate heptahydrate (Mallinckrodt Part No. 6066) in 10 ml of sterile DI water. Sodium azide (Fluka Part No. 71289) was added as a dry solid to the abiotic control. The unamended control microcosms and the abiotic microcosm received 10 ml additions of sterile DI water. Prior to addition all aqueous amendments were sparged with nitrogen gas (99.999%) for 10 minutes. After amendment addition, each microcosm was mixed within the glove box using a stainless steel shaft mounted propeller and a cordless drill. The #8 nitrate amended microcosm was placed in a water bath within the glove box that was operated at 52°C to 55°C. The other microcosms were incubated at room temperature.

The availability of the alternate terminal electron acceptors added to microcosms #4, #5, #6, and #8 was monitored periodically. The presence of oxygen in the hydrogen peroxide amended microcosm was determined using both a dissolved oxygen (DO) probe and a redox probe. The presence of nitrate and sulfate in microcosm #5, #6, and #8 was determined by withdrawing 3 ml of water through the wide bore three-way valve and teflon tubing shown in Figure F-1. The samples were withdrawn using 10 ml disposable syringes (Becton Dickinson Part No. 301029). The samples were filtered through 0.2 µm teflon syringe filters (Supelco Part No. 5-9235) and analyzed on a Dionex ion chromatograph using an AS-11 IonPac® Column (Dionex Part No. 44076). The results of these analyses were used to determine the availability of nitrate and sulfate. As the availability was seen to decrease, additional nitrate or sulfate was added to the respective microcosm(s).

The microcosms were all amended again in the manner described above on 8/7/97. On 8/8/97 DO and redox measurements confirmed the need to amend microcosm #4 with hydrogen peroxide again. Microcosm #4 was amended with hydrogen peroxide again as has previously been described above. All microcosms were again amended as described above on 8/15/97. On the occasion of each amendment,

the microcosm(s) amended were mixed with the stainless steel shaft mounted impeller and cordless drill. On 8/21/97 the #8 nitrate amended microcosm was removed from the cold water bath and the #7 unamended microcosm was placed in the water bath. Headspace analysis for methane was conducted on 8/28/98, and 10/6/98. On 10/9/98 the microcosms were removed from the glove box and refrigerated thus terminating the study.

Bacteria Enumeration - Methanogens (produce methane)

Methanogenic bacteria were enumerated using a most probable number (MPN) technique based on an enrichment medium utilized by Michael Godsy of USGS. One sample from the site was processed. The enrichment vials established 5 replicates and 5 dilutions in a glovebox and were incubated for a minimum of 1 month. Methane measurement of the headspace gas confirmed/refuted the existence of methanogens within a given vial. A MPN table was used to compute the most probable number of bacteria present in the sample. Additional details on the contents of the medium are available upon request.

Methanogenic bacteria are obligately anaerobic and are destroyed by any contact with oxygen. Coordination with the field crew was required in order to minimize the impact of atmospheric oxygen on these samples. Each vial within each MPN series was checked for the presence of methane by GC/FID after incubation, thus the sample received 25 qualitative GC runs.

The results of the MPN analysis appear in the attached Figure F-3. The MPN calculation estimated a methanogen concentration of 1.4 cells/ml of soil.

Bacteria Enumeration - Methanotrophs (degrade methane)

Methanotrophic bacteria were enumerated using unsaturated soil samples and incorporating a selective spread plate count technique with both methane and air environment. Twenty-four soil samples were processed. The sample IDs are found in the attached Table F-2. After plating a series of ten-fold dilutions on mineral nutrient agar media, the agar plates were incubated in a dessicator filled with a 50:50 mixture of methane and air. The incubation interval was 4 weeks. The colonies present after 3 days were counted and attributed to the growth of heterotrophic bacteria on the minute quanities of organic carbon present in the agar (Brock et. al., 1988). The plates were returned to the methane/air environment of the desication and the colonies were counted again after 4 weeks. Methanotrophic bacteria were defined as the difference between the total number of colonies per plate and the number of colonies counted after 3 days of incubation. The sample requirement for these analyses was a 120 ml widemouth bottle. A positive control was successful. No methatrophs were detected.

Methane Oxidation/Degradation (Methanotrophs)

Respirometry analysis of slurries was conducted using colocated soil and groundwater samples to evaluate information on the rate of methane degradation by methanotrophic bacteria at the Kingsford site. This work was conducted using soil samples collected from the site and incorporating a respirometer capable of methane/oxygen/carbon dioxide quantification. Four soil samples were analyzed which were GMGW-118, GM-48/64, GM-44/64, and GM47/83. Samples were first analyzed without methane present to determine the background respiration rate of heterotrophic bacteria that are degrading energy sources more complex than methane. Following this analytical run, the same samples were analyzed with methane provided to support any methanotrophs that are present. The rate of oxygen consumption

and carbon dioxide production representing methanotrophic methane oxidation can then be obtained by subtraction. These respirometry runs were carried out at a temperature that was representative of the groundwater temperature at the site.

The methane oxidation rate was calculated from the methane and oxygen consumption data. Though methane, carbon dioxide, and oxygen must equilbrate between the slurry and the headspace of the respirometry sample container before being measureable by the respirometer, the equilibration of oxgyen and methenae is more simplistic than that of carbon dioxide, which can form carbonates in the aqueous slurry which will damage the reliability of the data for rate calculations. Following the determination of methanotrophic oxygen consumption by difference, the following equation was used to determine the rate of methane oxidation concomittant with any given rate of oxygen consumption, stochiometrically as:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$

This was used as a check on the direct methane consumption measurements. The data gathered early in this study is the most defensible in terms of actual methane degradation rates *in-situ* as the number of both the numbers of heterotrophic bacteria and methanotrophic bacteria are likely to diverge from *in-situ* levels gradually over time and this divergence will bring with it inaccurate oxygen consumption data. Divergence of bacterial numbers could be caused by either differences in incubation temperature or differences in the availability of oxygen or methane.

The volume of soil required for this study on a per sample basis was 2 liters. A comparable volume of groundwater was also collected. Dissolved oxygen was used as a screening parameter in the field to determine if a given sample was to be submitted. If the groundwater was anaerobic, no methanotrophic bacteria was assumed present in that region of the groundwater system. No methane degradation was detected during the study.

Methane Generation Rate and Yield Coefficient

The objective of this portion of treatability work was to generate understanding of the rate of methane generation in the subsurface in the area from which the sample was collected. Additionally any inhibitory/toxic effects of the groundwater from the sampling region were investigated and the methane yield coefficient was determined. A microcosm study was established in a glove box on November 26, 1998. The soil sample used was identified as GM37B/293, or a subsurface soil sample collected from Monitoring Well GM-37B at a depth of 293 ft bls. In an anaerobic glovebox, soil that had been composited, was added to five 2-liter screw-top flasks until the volume consumed by the soil was equilvalent to 1400 ml. The total weight of the soil was recorded. Duplicate samples of the composited soil were submitted for VOC, SVOC, and TOC analyses by Encotech to establish baseline concentrations. The ARCADIS Geraghty & Miller Treatability Lab conducted one methanogen enumeration test on this composite soil sample according to the methodology discussed below. Each flask then received a groundwater aliquot treatment according to that shown in Table F-3. The groundwater was collected from the same subsurface interval as the soil. The initial groundwater TOC was separately determined by Encotech.

The flasks were sealed and placed in a incubator at 10 degrees C to simulate native groundwater temperature. Incubation was in a refrigerator operated at the above temperature. The microcosms were designed to be positive pressure and were also pressure tight. These characteristics made it possible to

incubate the anaerobic vessels in an aerobic environment. Pressure measurements in the headspace over time were used to measure the volume of gas generated over time. Periodic headspace gas sample analysis by GC/FID revealed the concentration of methane in the headspace. The performance of this periodic headspace gas analysis was determined by the build-up of pressure in the headspaces of the flasks. At the time of headspace gas analysis, each flask was vented to atmospheric pressure after a determination of the internal pressure. At two descretionary intervals during the incubation of these flasks TOC measurements were made on the liquid component of each microcosm. By limiting TOC measurements during the experiment to the liquid phase it is assumed that the preponderance of the TOC available to anaerobic microorganisms is soluble. At the conclusion of the incubation, which was determined by gas production declining to near zero, both the liquid and solid fractions of each microcosm were tested for TOC. Minimal methane generation was detected over the course of approximately 6 months. This portion of the treatibility test was terminated in June 1999.

Table F-1. Microcosms Treatment, Ford/Kingsford Site, Kingsford, Michigan.

Treatment Description	Microcosm Identification	Sodium Azide	Hydrogen Peroxide	Nitrate	Sulfate
Abiotic Control	#1	10,000 mg/l of volume			
Unamended Controls	#2, #3, #7				
H_2O_2 Amended	#4		8 mg/l of volume		
Nitrate Amended	#5, #8			50 mg/l of volume	
Sulfate Amended	#6				100 mg/l of volume

ARCADIS

Appendix H

3-D Visualization Data Directions for CD Rom

This CD-Rom contains visualizations of the physical setting and chemical characterization of Kingsford, Michigan. As described in the accompanying remedial investigation (RI) report, the visualizations were created using Environmental Visualization System, or EVS software. These files are an integral part of the presentation and understanding of the geology and constituent distribution in the groundwater. Additional information regarding EVS can be obtained from the internet, at http://www.ctech.com.

The attached files are in .HAV video clip format. HAV is a public domain video viewer, a copy of which is also included on the attached CD-Rom. The HAV program can be installed on a computer by clicking on the hav application file found under the read me folder and following the install directions. The visualization can be broadly categorized into Geology/Hydrogeology and Chemical Characterization. The following is a brief description of the attached files:

Geology/Hydrogeology

Six visualizations from the 3-D geologic model have been prepared to aid in the presentation of the site specific geology and hydrology. The six files are named as follows: Bedrock.HAV, Topobedrock.HAV, Boreholes.HAV, EWxsection.HAV, NSxsection.HAV, and Planexsection.HAV. The Bedrock and Topobedrock files illustrate the bedrock surface, while the EWxsection, NSxsection, and Planxsection files are east-west cross sections, north-south cross sections, and horizontal slice sections, respectively, across the site.

Chemical Characterization

Twenty-four visualizations from the 3-D chemical plumes have been prepared to aid in the presentation of chemical characteristics of the site. The 24 files, three files for each of the constituents modeled, are named as follows: 24DMP1.HAV, 24DMP2.HAV, and 24DMP3.HAV, 2MP1.HAV, 2MP2.HAV, and 2MP3.HAV, 4MP1.HAV, 4MP2.HAV, and 4MP3.HAV, MEK1.HAV, MEK2.HAV, and MEK3.HAV, Acetone1.HAV, Acetone2.HAV, and Acetone3.HAV, Acetic1.HAV, Acetic2.HAV, and Acetic3.HAV, TOC1.HAV, TOC2.HAV, and TOC3.HAV, and Methane1.HAV, Methane2.HAV, and Methane3.HAV.

The first file (designated with a "***1.HAV") is a visualization that represents the control points, or chemical concentration used from a groundwater sampling point. The second file (designated with a "***2.HAV") is a visualization that represents the compound plume from an "outside" view. The third file (designated with a "***3.HAV") is a visualization that represents the compound plume sliced through horizontally at various elevations.

The chemical compounds for the above abbreviations are as follows: 24DMP represents 2, 4-dimethlyphenol, 2MP and 4MP represent 2-methlyphenol and 4-methlyphenol respectively, MEK represents 2-butanone, Acetic represents acetic acid, Acetone represents acetone, TOC represents Total Organic Carbon, and Methane represents dissolved methane.

Executive Summary

This report describes the results of a biological community assessment (bioassessment) of the Menominee River in the vicinity of the Ford/Kingsford site in Kingsford, Michigan. ARCADIS Geraghty & Miller conducted this bioassessment on behalf of the Ford Motor Company and The Kingsford Products Company, in order to determine whether aquatic biota have been adversely impacted by groundwater migrating from the Ford/Kingsford site. This investigation was conducted in accordance with methods developed and employed by the U.S. Environmental Protection Agency (USEPA) and several state agencies in the Great Lakes region.

Methods

The Menominee River bioassessment specifically addressed the numbers and types of sediment-dwelling (benthic) macroinvertebrates and fish at locations upstream, adjacent to, and downstream of the site. Physical habitat and chemistry data were collected where feasible to help distinguish the cause of any differences in the macroinvertebrate and fish communities between locations.

Components of the benthic macroinvertebrate survey included the following:

- Benthic macroinvertebrates were collected at 25 sample locations. At each of 15 shallow (wadeable) locations, four replicate samples were collected using the traveling kicknet method. Qualitative sweep net sampling was also conducted at wadeable locations, to provide a more complete list of the species present. At 10 deep (non-wadeable) locations, four replicate samples were collected using artificial substrate samplers (Hester-Dendy type). The samplers were placed in the river for six weeks to permit colonization by invertebrates.

- A visual-based habitat assessment was conducted at wadeable locations according to the Michigan Department of Environmental Quality's (MDEQ) protocol. The assessment rated characteristics such as the embeddedness of the substrate (degree of siltation), availability of instream cover (such as logs and aquatic plants), diversity of microhabitats, and bank stability.

- Current velocity, water depth, and water quality parameters (temperature, conductivity, pH, dissolved oxygen) were measured at each location.

- Subsurface temperature gradients were measured, as a potential indicator of areas of upwelling groundwater. During the summer months, upwelling groundwater is colder than surface water.

- Sediment samples were collected for chemical analyses from all wadeable sample locations (coarse sediments prevented effective sample collection at non-wadeable locations). The chemicals of interest included phenolic compounds, dissolved metals, common ions (such as magnesium and bicarbonate), and pH. To provide the most appropriate measure of exposure to benthic invertebrates, most analyses were conducted on porewater extracted from the sediment samples using centrifugation. Phenolic compounds were analyzed in whole sediment, however, due to the potential for losses during centrifugation. Other analyses conducted to aid the interpretation of the survey results included total organic carbon and moisture content (for evaluation of chemical bioavailability) and ammonia and sulfide (potential naturally occurring stressors).

Components of the fish survey are summarized as follows:

- Ten 500-meter zones were sampled at night using electrofishing, which involves shocking the water, collecting and evaluating stunned fish, and releasing the fish back into the river. The fish were identified, counted, batch weighed by species, and examined for external anomalies.

- A visual-based habitat assessment was conducted for each sampling zone.

- Water quality parameters (temperature, dissolved oxygen, conductivity, water clarity) were measured at each zone. Water chemistry was not analyzed, because previous analyses indicated that chemicals would be present in the water column at very low concentrations (generally below detection limits).

- The average water depth in each sampling zone was calculated from the results of a bathymetry survey, conducted using multi-beam sonar.

Results

For the 15 wadeable macroinvertebrate sample locations, benthic community composition was strongly correlated with habitat characteristics but not with chemical concentrations or proximity to the site. Ten metrics were used to evaluate the benthic

community: abundance; number of taxa; diversity; Hilsenhoff Biotic Index (HBI); number of mayfly, stonefly and caddisfly taxa; percent mayflies; percent Tanytarsini midges; percent other diptera and non-insects; percent tolerant; and percent Cricotopus. Most of these metrics are based on the relative abundance of sensitive or tolerant species. In most cases, between 80% and 90% of the variation in metric values among locations was explained based solely on sediment embeddedness, or on a combination of embeddedness and river mile values. River miles reflect a large-scale habitat gradient due to the fact that the study area is located between two dams.

For the 10 non-wadeable macroinvertebrate sample locations, benthic community composition was very similar among locations. Habitat differences within the river channel were most likely less extreme than among wadeable locations, and the use of artificial substrate samplers further limited the influence of physical habitat conditions. All metric values for locations adjacent to the site were within the range of values observed at upstream and downstream reference locations.

Overall, the benthic macroinvertebrate community in the study area was of high quality. Sensitive species were observed at all sample locations. Benthic community metric values were not consistent with the "biological response signature" identified by Ohio EPA as being associated with chemical toxicity. Differences among locations that were associated with physical habitat characteristics were consistent with the biology of taxa that inhabit embedded sediments versus "silt-free" gravel substrates.

Fish community composition was strongly correlated with water depth. Shallower locations supported more fish of smaller size, including more species and higher diversity than deeper locations. This is consistent with the fact that fish tend to congregate in the shallows at night, and shallow backwaters tend to serve as "nursery" areas for many fish species. The sampling zones adjacent to the site actually exhibited the highest number and diversity of fish, because these were the shallowest areas sampled. The fish were visually observed to be plump and healthy, and external anomalies were very uncommon (occurring in less than 1% of the fish captured).

Biological Community Assessment

Biological community survey results provide no evidence of adverse impacts related to groundwater migrating from the Ford/Kingsford site. This assessment is based on the following findings:

- Biological community metrics within the study area are similar to those at reference locations that have similar habitat characteristics;

- Biological community metrics are generally closely correlated with physical habitat characteristics and are not correlated with chemical concentrations;

- Sample locations immediately adjacent to the area of affected groundwater do not deviate from the biological community characteristics that are predicted based on habitat conditions; and

- These results are in agreement with biological survey data collected by the Wisconsin Department of Natural Resources from additional study area locations during 1996-1999.

These findings are based on an extensive sampling effort, such that any impact occurring at an ecologically relevant scale would have been detected. The sampling locations included anticipated "hot spots" of groundwater upwelling, and the subsurface temperature results confirm that groundwater upwelling was occurring at some locations. Thus, it is apparent that constituents in groundwater are being sufficiently attenuated to prevent toxicity to the benthic macroinvertebrate community.

These conclusions also have implications for other components of the Menominee River ecosystem. Based on the high quality of the macroinvertebrate and fish communities, as well as the non-bioaccumulative nature of the chemicals of interest, the river should provide an excellent prey base for aquatic-feeding wildlife. At the opposite end of the food chain, the high quality of the benthic macroinvertebrate and fish communities indicates that important ecological functions of the groundwater-surface water transition zone are not impaired. The transition zone may provide important habitat, enhanced degradation of contaminants, enhanced nutrient and carbon cycling, and production of a food source (microbial biofilms) for benthic macroinvertebrates. These functions are potentially important to the ecosystem. If they were impaired by groundwater migrating from the site, then effects on the benthic macroinvertebrate community would have been observed.

1. Introduction

This report describes the results of a biological community assessment (bioassessment) of the Menominee River in the vicinity of the Ford/Kingsford site in Kingsford, Michigan. ARCADIS Geraghty & Miller conducted this bioassessment on behalf of the Ford Motor Company and The Kingsford Products Company, in order to determine whether aquatic biota have been adversely impacted by groundwater migrating from the Ford/Kingsford site. This investigation was conducted in accordance with methods developed and employed by the USEPA and several state agencies in the Great Lakes region (Barbour et al., 1999; Bode et al., 1991; Lazorchak et al., 1999; MDEQ, 1997; WDNR, 1997; 1998; Yoder and Rankin, 1995).

Specific objectives of this bioassessment are:

- To determine whether the numbers and types of benthic (sediment-dwelling) macroinvertebrates in the Menominee River adjacent to the area of affected groundwater are indicative of chemical toxicity; and

- To determine whether the numbers, types, and health of fish in the Menominee River adjacent to the area of affected groundwater are indicative of chemical toxicity.

1.1 Background Information

The Menominee River forms the border between northeastern Wisconsin and the upper peninsula of Michigan. The Menominee River is formed by the junction of the Brule and Michigamme Rivers near Florence, Wisconsin. From this point, the river flows 118 miles to the southeast before discharging into Green Bay, an arm of Lake Michigan. The Menominee River Basin encompasses over 4,000 square miles of land, most of which is forested. Several major waterfalls and rapids formerly existed within the Menominee River, along the boundary between the Canadian Precambrian shield and adjacent sedimentary bedrock. Most of these areas have been impounded by dams, with the river being used for hydropower production (NRCS, 1992; Thuemler and Schnicke, 1992).

The Ford/Kingsford site is located in the City of Kingsford, in Dickinson County, Michigan. Groundwater near the Menominee River is affected by historical disposal

activities in areas known as the former Northeast and Southwest Pits. The principal source of contamination was waste water containing dissolved organic material (including methylated phenolic compounds) from wood pyrolysis processes. The dissolved organic material was carried deep into the groundwater aquifer, where biodegradation of the material is taking place. Biodegradation products include acetic acid and methane. Additionally, the reactive nature of the biodegradation process results in some solubilization of minerals from the soils comprising the groundwater system. The affected groundwater lies adjacent to a small portion of the Menominee River approximately 2500 feet in length, located between the Ford Dam (also called Kingsford Dam) and the Big Quinnesec Dam.

Groundwater near the Menominee River has been investigated through chemical analyses and toxicity testing. The comparison between chemical concentrations and MDEQ water quality values is described in detail in the draft Remedial Investigation Report (ARCADIS Geraghty & Miller, 2001). Chemicals of potential concern identified from this first-step screening process include certain phenolic compounds (2,4-dimethylphenol, 2-methylphenol, 3-methylphenol, phenol), acetic acid, and metals (manganese, barium, vanadium).

In addition to the evaluation of measured chemical concentrations, the MDEQ required toxicity tests to be conducted using groundwater collected from wells near the Menominee River. The tests were conducted using standard methods developed for whole-effluent toxicity (WET) testing. Some groundwater samples were toxic to fathead minnows (*Pimephales promelas*) and/or daphnids (*Daphnia magna*). Standard Toxicity Identification Evaluation (TIE) procedures were implemented to identify classes of chemicals contributing to the observed toxicity. In general, toxicity appeared to be due to a combination of iron, bicarbonate, and phenolic compounds. Groundwater toxicity test and TIE results are presented and compared to chemical concentrations in Appendix A.

The scientific literature provides little precedent to establish the ecological relevance of toxicity test results for groundwater. However, the application of these results is generally analogous to the monitoring of effluent discharges to surface water through WET testing. During the past several years, the USEPA and others have embarked on a mid-course review of WET testing (Ausley, 2000). Based on a technical review of the merits and limitations of WET testing, the appropriate use of this type of information is as an indicator of the need for further evaluation of risks to aquatic life (Chapman, 2000). Due to factors such as the inability to reliably predict instream biological condition from WET test results (Diamond and Daley, 2000), variability of

test results (Warren-Hicks et al., 2000; Moore et al., 2000a), and the likelihood of false positives (Moore et al., 2000b), WET testing does not provide a definitive determination of ecological impact (Chapman, 2000). The ability to predict surface water impacts based on WET test results is expected to be lower for groundwater toxicity tests than for whole effluent tests, because of the diffuse nature of groundwater discharge, inherent differences in the geochemistry of groundwater versus surface water, and various attenuation processes that occur before groundwater becomes surface water. Therefore, a bioassessment was conducted to provide a more direct and reliable method of assessing conditions in the Menominee River area of interest.

1.2 Study Design

This report presents a bioassessment of benthic macroinvertebrates and fish in the Menominee River area of interest. Bioassessments are direct measurements of biological community characteristics that have the potential to show impacts related to human activities. Bioassessment methods are often applied to aquatic ecosystems, based on the recognition that sole reliance on chemical and toxicity standards can sometimes result in undesirable outcomes: (1) chemical and toxicity water quality standards may all be met, but ecological integrity may not be attained, or (2) ecological integrity may be satisfactory even though water quality standards are not attained. With rigorous and robust data, bioassessments are a more accurate indicator of anthropogenic impacts than chemical and toxicity evaluations, because they directly measure the ecological resource that is being protected (USEPA, 2000a).

Twenty-five locations in the Menominee River were evaluated for benthic invertebrate community quality. Benthic invertebrate communities are frequently used in bioassessments, because they integrate the effects of chemical constituents over time, and their mobility is low enough to support spatial comparisons. Benthic invertebrates live in or on the sediment and, as such, experience greater exposure to migrating groundwater than aquatic organisms. Locations were sampled upstream, adjacent to, and downstream of the area of affected groundwater. In order to facilitate distinguishing between biological responses to physical habitat conditions and impacts related to migrating groundwater, physical habitat and sediment chemistry were characterized at the benthic invertebrate sample locations, where feasible.

Fish community quality was also assessed, for ten sampling zones within the area of interest. Fish in the Menominee River experience less exposure to constituents from migrating groundwater than benthic invertebrates, due to (1) dilution of groundwater by a large volume of surface water, and (2) the fact that the chemicals of potential

concern in the study area are not bioaccumulative in fish (USEPA, 1995). However, fish could potentially be affected by a diminished food supply if benthic invertebrates were significantly impacted by toxicity. Surface water chemistry was not characterized in conjunction with the fish survey, because chemical concentrations were generally expected to be very low throughout the area of interest, based on past analyses (ARCADIS Geraghty & Miller, 2001). Physical habitat characteristics were evaluated for the fish sampling zones.

1.3 Report Organization

The remainder of this report is organized in the following sections:

- Methods: Section 2 describes the procedures used in the habitat-based identification of sample locations, benthic invertebrate sampling, fish sampling, physical habitat evaluation, physicochemical analyses, and statistical evaluations.

- Results: Section 3 summarizes the biological, habitat, and physicochemical data collected for the bioassessment and provides a statistical analysis of the relationship between biological community quality, habitat characteristics, and chemistry.

- Discussion: Section 4 integrates the findings of this and other biological surveys of the Menominee River to assess the overall quality of the aquatic ecosystem.

- Summary and Conclusions are provided in Section 5.

- References

2. Methods

2.1 Sampling Locations

The identification of sample locations was based on several factors, including:

- The spatial extent of affected groundwater adjacent to the Menominee River,
- Large-scale physical habitat features of the study area, and
- Water depth and substrate characteristics, as determined from multi-beam and side-scan sonar surveys.

The characterization of the study area and selection of macroinvertebrate and fish sampling locations is described below.

2.1.1 Study Area Description

Figure 2-1 shows the locations of groundwater monitoring wells adjacent to the river. As described in Appendix A, toxicity tests have been conducted by exposing surface water organisms (fathead minnows and *Daphnia magna*) to groundwater collected from these wells. Monitoring well GM-25B has exhibited the highest level of toxicity in these tests. Groundwater samples collected from certain wells as far northwest as GM-5 and as far southeast as GM-27A were also classified as toxic to surface water organisms in laboratory tests (although samples from many of the groundwater wells within this area have not consistently elicited toxicity). Thus, the area adjacent to affected groundwater is approximately defined as river miles (RM) 99.9 through 100.4 (Table 2-1). Notable site-related features in the Menominee River within the study area include an area of continuous gas bubbling (venting methane) near Staff Gauge #2 (RM 100.31) and a seep exhibiting odor and sheen that is currently subject to interim containment (RM 100.0). Sampling locations were selected to encompass the area adjacent to the affected groundwater as well as reference locations.

The selection of reference locations required an understanding of key features affecting physical habitat conditions in the area of interest. The most important, large-scale features affecting aquatic habitat in this area are the upstream Ford Dam (RM 101.5) and the downstream Big Quinnesec Dam (RM 96.0). The Ford Dam influences the study area by (1) acting as a sediment trap, resulting in low levels of fine-grain sediment downstream of the dam, (2) releasing varying amounts of water based on electrical generation needs, resulting in fluctuating water levels, and (3) limiting

seasonal flooding (USGS, 2000). The Big Quinnesec Dam influences the study area by impounding the river, resulting in deeper water, slower flow, and greater sedimentation. Before construction of the Big Quinnesec Dam, a reach of high gradient water and rapids (4.2 miles with 49 feet of fall) extended approximately as far upstream as RM 100.2; this reach is now permanently flooded (Thuemler and Schnicke, 1992). The study area thus lies within a physical habitat gradient influenced by both dams. Reference locations were therefore selected between the two dams, both upstream and downstream of the study area, to encompass the range of habitat conditions in areas known to be unaffected by the site.

At a smaller scale, water depth and substrate type are very important in determining both (1) the types of organisms present at a given location and (2) the appropriate sampling methodology. These characteristics were evaluated through multi-beam and side-scan sonar surveys and concurrent sediment grain size analyses. The sonar surveys were conducted by Superior Special Services during June 5-9, 2000 under the supervision of ARCADIS Geraghty & Miller. Multi-beam sonar provided detailed bathymetry data for the study area (Figure 2-2), and side-scan sonar provided an image of the substrate (Appendix B). Sonar data collection was limited to areas with water depths greater than three feet at the time of the survey. Water depths were interpolated for shallower areas (see Figure 2-2). As a supplement to the side-scan sonar, surface sediment samples were collected for analysis of grain size and total organic carbon. Twenty grab samples of shallow surface sediment (top 10-15 cm) were collected at the time of the side-scan sonar survey.[1]

The data collected from these surveys support the following generalizations:

- Shallow (wadeable) areas are generally concentrated along the Michigan side of the river. Few wadeable areas are present along the Wisconsin shoreline.

- The substrate within the area of interest consists primarily of gravel with varying amounts of sand. Soft sediment substrate is quite limited in extent.

---

[1] Sampling for grain size and total organic carbon was used to help delineate substrate types; the sample locations do not coincide with the locations subsequently selected for biological and chemical sampling.

- Submerged logs are abundant within the study area and are generally of similar length. Several areas containing a high density of submerged logs were identified.

- Many large boulders protrude from the river bottom, although their distribution is more sporadic than that of the submerged logs.

Finally, the following areas were avoided during the selection of sample locations, based on the expectation that biological community characteristics would differ from those in the area of interest due to factors unrelated to the site:

- Area immediately downstream of the Ford Dam,

- Little Popple River confluence,

- Wetlands near RM 100.0, and

- Area adjacent to the discharge from the Kingsford/Iron Mountain Wastewater Treatment Plant.

2.1.2 Benthic Macroinvertebrate Sampling Locations

Twenty-five locations were selected for benthic macroinvertebrate sampling and concurrent sediment sampling and habitat characterization. Sample locations were selected to represent shallow and deep habitat types. Submerged log density was considered in the selection of deep-water sample locations. Sediment grain size characteristics were also considered in the field during the final selection of sampling locations, to ensure that the reference locations encompassed the range of sediment types encountered at study area sample locations.

Figure 2-3 shows the benthic macroinvertebrate sampling locations for this study. Sample locations were confirmed using Global Positioning Satellite (GPS) technology. Fifteen wadeable locations were sampled (water depths <1 meter), including two locations on the Wisconsin shoreline and thirteen locations along the Michigan shoreline. Ten non-wadeable locations were sampled (water depths >1 meter), providing approximately equal representation of the Michigan and Wisconsin sides of the river channel. The majority of non-wadeable locations correspond to areas of high submerged log density. The reason for this is that this habitat type is expected to support greater biomass and diversity of macroinvertebrates and is therefore more important ecologically than areas lacking submerged logs. Additionally, the artificial

substrate samplers used at non-wadeable locations are designed to mimic submerged wood.

The study design includes several reference locations which are known to be unaffected by the site. Multiple reference locations are included in the study design because the use of a reference envelope provides a more accurate characterization of reference conditions than reliance on a single reference location. The following are considered reference locations (see Figure 2-3): RBM-1, -2, -14, -15, -16, -24, and -25. Additionally, the following locations are most likely outside the influence of potentially affected groundwater: RBM-3, -13, -17, and -23.

Wadeable sampling locations were approximately 50 meters in length, and non-wadeable sampling locations were approximately 100 meters in length. River mile designations for macroinvertebrate sampling locations are shown in Table 2-2.

2.1.3 Fish Sampling Zones

Fish sampling was conducted within the relatively shallow area between the shoreline and the deep river channel, as recommended by Simon and Sanders (1999). Sampling the deep portion of a river channel does not provide significant additional information on fish community quality (Simon and Sanders, 1999). Fish sampling zones were 500 meters in length, which allowed nearly complete coverage of the area of interest. Five pairs of sampling zones were selected, one on each side of the river, for a total of ten sampling zones (Figure 2-4). Locations RBF-1, -2, -9, and -10 are considered reference locations. In addition, locations RBF-7 and RBF-8 are most likely outside the influence of potentially affected groundwater. River mile designations for the fish sampling zones are shown in Table 2-3.

2.2 Benthic Macroinvertebrate Survey

2.2.1 Benthic Macroinvertebrate Sampling Procedures

The benthic macroinvertebrate sampling was conducted during July 23-27, 2000 by EA Engineering, Science & Technology, under the supervision of ARCADIS Geraghty & Miller. Two separate sampling methods were employed to characterize benthic invertebrate community quality: (1) direct sampling of natural substrates at wadeable locations, and (2) use of artificial substrate samplers at non-wadeable locations. The benthic macroinvertebrate sampling methods are based on the following:

- U.S. EPA's *Rapid Bioassessment Protocols for Use in Wadeable Streams and Rivers* (Barbour et al., 1999);
- U.S. EPA's Environmental Monitoring and Assessment Program (EMAP) methods for measuring the ecological condition of non-wadeable rivers and streams (Lazorchak et al., 1999);
- Bioassessment methods developed for New York State streams and rivers (Bode et al., 1991); and
- Benthic invertebrate sampling methods used by the Wisconsin Department of Natural Resources (WDNR) in surveys of the Menominee River (WDNR, 1997; 1998; R. Lillie, personal communication).

The Rapid Bioassessment Protocols are widely used and provide a useful starting point for the development of a site-specific sampling plan. However, they are designed only for wadeable waters and provide only semi-quantitative information (no replication). The EMAP sampling protocols are somewhat more quantitative, as are the New York State methods. Additionally, the New York methods provide an alternative sampling protocol for deep waters. The WDNR methods are similar to the Rapid Bioassessment Protocols and are useful as a site-specific precedent.

2.2.1.1 Wadeable Sampling

Benthic macroinvertebrates were collected at each wadeable sample location using the traveling kicknet (TKN) method described by Bode et al. (1991). The TKN method uses a rectangular box-type kicknet (800-900 μm mesh). The net is placed on the substrate approximately 0.5 meter downstream of the collector. The collector proceeds to disturb the substrate while moving in an upstream direction bringing the net along the bottom so that dislodged organisms will be washed into the net. Sampling is conducted for a distance of five meters and for two to five minutes (Bode et al. 1991, Bode and Novak 1995, Bode et al. 1996). Four replicate TKN samples were collected at each of the 15 locations. To the extent possible, TKN sampling was conducted on coarse gravel substrate within each 50-meter sampling zone, to maximize comparability among locations. Replicate transects were parallel to one another and were successively further from shore, to encompass a gradient of water depth.

As a supplement to the TKN samples, macroinvertebrates were collected qualitatively using a triangular dip/sweep net (800-900 μm mesh) and sampling all available habitats (e.g., rocks, sand, snags, macrophytes, etc.). For each habitat, the collector

disturbed the substrate and then repeatedly swept through the area with the net to collect invertebrates that had been dislodged. In addition, the collector examined large substrates (e.g., logs and boulders) as well as the surrounding area for taxa that might otherwise have been missed (e.g., crayfish, mussels, and cased caddisflies). Collections from all habitats at a particular location were combined into one sample. The types of habitats sampled were recorded on a field collection data sheet at each location.

2.2.1.2 Non-Wadeable Sampling

Sampling at non-wadeable locations was conducted using modified Hester-Dendy artificial substrates (OEPA, 1987). Each Hester-Dendy sampler is comprised of eight 3"x 3"x1/8" hardboard plates variably spaced along a 4" eyebolt. The total surface area of one sampler is approximately one square foot. Four replicates Hester-Dendy arrays (each consisting of three Hester-Dendy samplers) were deployed from a boat at each of the ten non-wadeable locations during the July sampling event. The Hester-Dendy samplers were fixed to cinder blocks and set on the river bottom. Each replicate was marked with a surface float and an identification label.

The Hester-Dendy samplers were retrieved during September 5-8, 2000, after a six-week colonization period. Each cinder block was lifted close to the water surface, and a fine mesh sieve was placed under the block prior to breaking the water surface. The Hester-Dendy samplers were placed in containers with preservative, together with any organisms that had moved from the samplers into the sieve during the retrieval process. Of the 40 Hester-Dendy replicates, three were lost due to vandalism or other causes, and a fourth was unusable due to poor sample preservation. At least three replicates were successfully retrieved at each location, however.

2.2.1.3 Sample Preservation and Processing

All benthic macroinvertebrate samples were preserved in the field with a 10% formalin solution and transported to the EA laboratory for processing and analysis. Upon arrival at the laboratory, all benthic macroinvertebrate samples were assigned a log number to identify and track the samples through the various stages of processing. Each benthic macroinvertebrate sample was rinsed using a number 60-mesh sieve (250 µm) to remove preservative. Any remaining large debris was checked for organisms and discarded.

Random sub-sampling was employed to reduce the number of organisms per sample to a manageable sample size. A subsample of 150 organisms was removed from each benthic macroinvertebrate sample (WDNR, 1997; 1998). This was conducted by evenly distributing the sample debris in a gridded white enamel pan, randomly choosing grids, and removing the organisms within each grid under a 10X magnifying lamp. Grids were chosen and organisms removed until the sorter removed 150 or all the organisms present in the sample. The percentage of grids cleared was used subsequently to extrapolate the total number of organisms of each taxon present in the sample.

Chironomidae were cleared in 10% KOH and mounted in CMC-10 prior to identification. Organisms were identified to the lowest practical taxon using the most current literature available. Most organisms were identified to genus or species, with the exception of worms and certain mollusks, which were generally identified to the family level.

2.2.2 Physical Habitat Assessment

2.2.2.1 Visual-Based Habitat Assessment

A visual-based, qualitative habitat assessment was conducted for each of the 15 wadeable macroinvertebrate sample locations. The MDEQ's GLEAS 51 habitat survey protocol was used (Table 2-4). This protocol involves the determination of habitat quality scores for nine macrohabitat characteristics. Additionally, a description of substrate characteristics (grain size, embeddedness), submerged vegetation and other instream cover (type and extent), and any other notable habitat features was recorded. This type of assessment was not conducted for non-wadeable macroinvertebrate sampling locations, due to water depth (i.e., inability to see the river bottom).

2.2.2.2 Water Quality

Water quality parameters were measured at all macroinvertebrate sample locations. Water quality parameters (temperature, conductivity, pH, and dissolved oxygen) were measured using a YSI probe. A separate pH meter was used during the September sampling event. These measurements were made as close as possible to the river bottom within the water column. At wadeable locations, replicate measurements were recorded at the upstream and downstream ends of the sampling zone. At non-wadeable locations, measurements were recorded mid-zone during both the Hester-Dendy sampler placement and retrieval. Due to equipment malfunction, dissolved oxygen

readings from the July sampling event and pH readings from the September sampling event were unusable.

2.2.2.3 Water Depth and Current Velocity

During macroinvertebrate sampling, water depth was measured directly at the location of each replicate TKN transect for wadeable locations and each replicate Hester-Dendy sampler array for non-wadeable locations. Current velocity was measured as close to the river bottom as practical, using an electronic meter. Measurements were recorded at the location of each replicate TKN transect for wadeable locations and each replicate Hester-Dendy sampler array for non-wadeable locations. Current velocity was measured at non-wadeable locations during Hester-Dendy set and retrieval.

2.2.2.4 Subsurface Temperature

Shallow subsurface sediment temperature was measured during the July sampling event as a potential indicator of locations of groundwater flow into the river. Subsurface temperature can be used for this purpose during summer or winter, when surface water temperature differs significantly from the temperature of groundwater (Hendricks and White, 1991; White, 1993). A 24-inch, heavy-duty temperature probe was inserted into the sediment, and temperatures were recorded at 4-inch intervals to a depth of 24 inches or the limit of penetration. Where possible, this procedure was conducted at three locations within each macroinvertebrate sampling zone. At most non-wadeable locations and some wadeable locations, the substrate was too rocky for the temperature probe to penetrate fully.

2.2.3 Sediment Chemistry

Chemical analyses were conducted to facilitate the evaluation of whether spatial patterns of benthic invertebrate community quality and potential contaminant concentrations coincide. Surface sediment was sampled to correspond with the appropriate exposure point for benthic invertebrates. Surface water samples were not analyzed, based on the lack of detectable chemical concentrations in past analyses and the high degree of dilution of migrating groundwater. Fish tissue also was not analyzed, because the chemicals of interest for this study are not significantly bioaccumulative (USEPA, 1995).

2.2.3.1 Sediment Sampling

Surface sediment samples (top 10-15 cm) were collected for chemical analysis by ARCADIS Geraghty & Miller. Grab sampling was not practical due to the coarse nature of the substrate. Therefore, sediment was collected using an AMS split core sampler with a stainless steel or acrylic liner. The core sampler was augered into place. Sample integrity could not be maintained using this method at non-wadeable sample locations; therefore, sediment sampling was limited to wadeable macroinvertebrate sample locations.

Approximately 2.5 liters of sediment were collected at each location. Individual core samples were collected from representative locations throughout the macroinvertebrate sampling zone. Sediment was placed in a stainless steel container and minimally homogenized, then distributed to sample jars (no headspace) and placed on ice. Equipment rinsate blanks and matrix spike/matrix spike duplicate (MS/MSD) samples were also collected. General characteristics of the sediment (e.g. color, sediment type) were recorded.

2.2.3.2 Chemical Analyses

Extensive sediment toxicology research has demonstrated that the concentrations of chemicals in sediment porewater are much better predictors of toxicity than whole-sediment concentrations (e.g., Ankley et al., 1996; Di Toro et al., 1991). Therefore, most analyses for this study were conducted directly on sediment porewater. Sediment porewater was extracted at the Columbia Analytical Services laboratory (Kelso, WA) according to the U.S. Army Corps of Engineers Dredged Material Management Program protocol (Hoffman, 1998). This protocol employs centrifugation under an anaerobic atmosphere. Sediment porewater was analyzed for:

- Major ions (sodium, calcium, magnesium, potassium, chloride, sulfate, and bicarbonate);
- Dissolved metals (iron, manganese, barium, and vanadium) and hardness;
- pH (as an indicator of acetic acid); and
- Ammonia and sulfide (potential naturally occurring stressors).

Porewater was filtered (0.45 micron filter) prior to metals analysis.

Due to the potential for chemical losses due to volatilization during porewater extraction, phenolic compounds were not analyzed in porewater. Instead whole-sediment samples were analyzed by STL Savannah Laboratories (Savannah, GA) for:

- Phenolic compounds (phenol, monomethylphenols, and dimethylphenols), and
- Total organic carbon and percent moisture.

The concentrations of phenolic compounds in porewater were then estimated from whole-sediment concentrations, based on the sediment's organic carbon and moisture content (Fuchsman and Barber, 1999). Analytical methods for porewater and whole-sediment analyses are summarized in Table 2-5.

2.3 Fish Survey

2.3.1 Fish Sampling Procedures

Fish sampling was conducted during September 5-8, 2000. Fish were collected by boat electrofishing, which involves shocking the water and collecting the stunned fish by net. The electrofishing was conducted at night, within the relatively shallow area between the shoreline and the deep river channel. These methods are consistent with recommendations for fish sampling in large rivers (Simon and Sanders, 1999). Fish sampling was conducted by EA Engineering, Science & Technology under the supervision of ARCADIS Geraghty & Miller.

All sampling zones were 500 meters in length and were measured at each zone using a hip chain along the shoreline. Coordinates were recorded using a GPS unit at the beginning and end of each zone.

Fish were sampled using pulsed DC boat electrofishing at each of the 10 designated zones. The electroshocker was powered by a 5000-watt generator with output controlled by a Coffelt Model VVP-15 pulser. Output settings generally were maintained at 60 pulses per second and 60-80 percent pulse width. The sampling crew consisted of one driver and one dipper. A 3/16" mesh dip net was used to collect stunned fish. Electrofishing proceeded in a downstream direction within each zone.

All fish collected within each zone were identified, counted, checked for anomalies, and then batch weighed by species. To the greatest extent possible, adult and juvenile fish were processed in the field and returned to the water alive. However, some small

fish of uncertain taxonomy and/or extreme abundance were preserved in formalin and brought back to the laboratory for further examination and processing.

Identification of preserved fish was made using the best and most recent keys to midwestern fishes (Pflieger, 1975; Smith, 1979; Trautman, 1981; Becker, 1983; Page, 1983). Nomenclature followed the most recent guidance of the American Fisheries Society (Robins et al. 1991). As in the field sampling, the number of individuals and batch weight were determined for each species, and any physical anomalies were noted.

2.3.2 Physical Habitat Assessment

For fish sampling zones, the physical habitat assessment included the visual-based habitat assessment protocol described in Section 2.2.2.1, measurement of water quality parameters, and calculation of average water depths. Measurement of current velocity was not practical for fish sampling zones, due to the large size of each zone and the high degree of spatial variation in current velocity.

Average water depths were calculated from the multi-beam sonar data. Each zone was assumed to extend 25 feet from the shoreline into the river, for the purpose of this calculation. An average water depth could not be calculated for sample location RBF-2, which was located upstream of the area surveyed. Location RBF-1 was partially upstream of the area surveyed, and the average water depth in this zone was estimated based on the data for the surveyed portion of the zone.

Water quality parameters were measured at the upstream end of each electrofishing zone. Water temperature, conductivity, dissolved oxygen, and water clarity (i.e., Secchi disk depth) were measured. Secchi depth was measured using a standard Secchi disk. Since electrofishing was conducted at night, Secchi depths were measured using a spotlight. The remaining parameters were measured at mid-depth in the water column using electronic meters.

2.4 Statistical Analyses

For sampling methods that employed replication (TKN and Hester-Dendy), statistical comparisons were made between study area and reference locations for benthic macroinvertebrate community metrics. Analysis of variance (ANOVA) was conducted using Excel® software (Microsoft, 1999) to determine whether any locations were significantly different ($\alpha = 0.05$). In cases where significance was indicated, the

Bonferroni multiple comparison procedure was used to identify which study area locations were significantly different than each reference location. The minimum detectable difference for comparisons between study area and reference locations was calculated using Axum® software (MathSoft, 1999), based on α equal to 0.05, β equal to 0.8, a sample size of 4, and the average relative standard deviation for each biological metric.

Linear and non-linear regression analyses were conducted using DataFit® curve-fitting software (Oakdale Engineering, 2000), to evaluate the relationship between habitat and chemical conditions and biological community metrics. Logistic equations were derived according to the following equation:

$$y = \frac{a-d}{1+(x/c)^b} + d$$

where x = habitat or chemical value, y = biological metric, a = asymptotic maximum of y, b = slope parameter, c = x value at inflection point, and d = asymptotic minimum of y. Three-dimensional curve-fitting was conducted by substituting the following function for x:

$$F = mx_1 + nx_2$$

where m and n are constants and x_1 and x_2 are independent habitat or chemical variables.

3. Results

3.1 Benthic Macroinvertebrate Survey

Results of the physical habitat and sediment chemistry analyses are described in Sections 3.1.1 and 3.1.2. Benthic macroinvertebrate community results are described in relation to habitat and chemical conditions in Section 3.1.3.

3.1.1 Physical Habitat

Results of the visual-based habitat assessment for wadeable macroinvertebrate sample locations are shown in Table 3-1. Habitat conditions varied considerably among locations. Total habitat scores ranged from 53 (location RBM-7) to 120 (location RBM-4). For comparison, the MDEQ (1997) classifies total habitat scores as follows: excellent (107 or higher), good (71-106), fair (35-70), or poor (less than 35). Habitat metrics that showed little variation among sample locations included flow stability and all riparian and bank structure metrics. Some of the remaining metrics were combined to minimize redundancy. Specifically, the "embeddedness/siltation" and "bottom deposition/sedimentation" metrics were summed to create a total "embeddedness" score, and the "velocity:depth habitat variability" and "pools/riffles/runs-bends" metrics were summed to create a total "habitat diversity" score. Together with the "bottom substrate and available cover" metric and total habitat scores, these values provide a basis for assessing the spatial relationship between physical habitat conditions and benthic macroinvertebrate community characteristics.

Significant water level fluctuation (1 to 2 feet) was observed during the sampling events, due to dam-related flow regulation. The river shoreline was thus periodically inundated and re-exposed throughout the study area. During low water, the exposed shoreline was observed to be poorly vegetated. Aquatic macrophytes were abundant elsewhere in the river, including most sample locations. The most abundant macrophyte species was water celery (*Vallisneria americana*). Other species included *Elodea* spp. and large-leaved pondweed (*Potomogeton amplifolius*). Woody debris was also prevalent at many sample locations.

A visual-based habitat assessment was not possible for the non-wadeable sample locations, due to the depth of water. However, the side-scan sonar results for the study area (Appendix B) allowed the development of a qualitative ranking of the extent of large-scale cover, in the form of logs or boulders. These ranking values are shown in Table 3-2.

Water quality measurements (temperature, conductivity, pH), water depth, and current velocity data are summarized for the macroinvertebrate sample locations in Table 3-3. Replicate measurements are provided in Appendix C. Water column temperature, pH, and conductivity showed little variation among locations and are unlikely to contribute to differences in biological community quality within the study area. Water depth and velocity showed greater variation and are considered further in Section 3.1.3.

Subsurface temperature is primarily of interest as a means of identifying areas of upwelling groundwater. Temperatures at the sediment surface averaged 20.5°C, whereas groundwater temperature was approximately 10°C. Temperatures at a depth of 24 inches ranged from 8.9°C to 18.2°C, indicating that groundwater upwelling was occurring at some but not all sample locations. The maximum depth of penetration varied among locations; therefore, the average temperature drop per inch was calculated for each location to facilitate comparisons. Data were not included if the maximum depth was less than 12 inches, however. Subsurface temperature measurements are provided in Appendix C and summarized in Table 3-4 and Figure 3-1. Groundwater upwelling was clearly occurring at location RBM-4, where temperatures similar to that of groundwater were observed within the top 24 inches of sediment. Among the remaining locations, RBM-5 and RBM-9 exhibited the greatest temperature drop per inch. These locations correspond to Staff Gauge #2 and the seep area, where groundwater discharge was previously suspected based on visually observed phenomena (see Section 2.1.1).

3.1.2 Sediment Chemistry

Table 3-5 presents the results of sediment porewater analyses for wadeable sample locations. Whole-sediment analytical results are shown in Table 3-6. The relationship between chemical concentrations and benthic macroinvertebrate community quality is evaluated in Section 3.1.3.

Concentrations of iron, major ions (sodium, calcium, magnesium, potassium, chloride, sulfate, and bicarbonate), and phenolic compounds are of interest because these constituents were identified as contributing to groundwater toxicity in laboratory tests (Appendix A). Major ion concentrations in all porewater samples were well below levels expected to cause toxicity to invertebrates and fish (Mount et al., 1997; Tietge et al., 1994). Iron concentrations approached potentially toxic levels (low mg/L; see Appendix A) in certain samples (RBSD-2, -11, -15), but the spatial pattern of iron concentrations in porewater showed no relationship to the site. Indeed, two of the three highest iron concentrations were reported from reference locations, including the

highest iron concentration (4.2 mg/L, RBSD-15). Historical iron mining operations in the area suggest that elevated iron concentrations are naturally occurring.

The only phenolic constituent detected was 3-/4-methylphenol, which was reported for two sediment samples (RBSD-6 and RBSD-8). These samples were collected from locations adjacent to the area of affected groundwater. Concentrations of 3-/4-methylphenol in porewater were estimated using the equilibrium partitioning approach (Di Toro et al., 1991) modified for less hydrophobic compounds (Fuchsman and Barber, 1999):

$$Porewater\ concentration = \frac{Sediment\ concentration}{\left(f_{oc} \times K_{oc}\right) + \left(\frac{1 - f_{solids}}{f_{solids}}\right)}$$

where:

f_{oc} = Sediment-specific fraction organic carbon;

K_{oc} = Chemical-specific organic carbon-water partition coefficient, calculated from the octanol-water partition coefficient (K_{ow}) (Di Toro et al., 1991); and

f_{solids} = Sediment-specific fraction solids.

Based on a log K_{ow} of 1.96 (Karickhoff and Long, 1995), the porewater concentrations of 3-/4-methylphenol in samples RBSD-6 and RBSD-8 are estimated as 120 µg/L and 90 µg/L, respectively. These concentrations are slightly higher than the MDEQ's Final Chronic Value (FCV) for 3-methylphenol of 71 µg/L but much lower than the Final Acute Value (FAV) of 1,271 µg/L. As described in Section 4.2, the aquatic toxicity literature indicates that 3-/4-methylphenol is unlikely to cause toxicity at the concentrations estimated in porewater. Since the FAV is not exceeded, and the FCV would be adjusted for mixing at levels far in excess of those observed, 3-/4-methylphenol is not a compound of concern. The MDEQ has not adopted water quality values for 4-methylphenol. In contrast to groundwater samples, 2,4-dimethylphenol was not detected in any sediment sample.

Although not implicated as contributing to groundwater toxicity (Appendix A), several constituents were measured in sediment porewater because they exceeded an FCV in some groundwater samples. These include barium, manganese, and vanadium. Additionally, pH was measured as a surrogate for acetic acid, because analytical methods for acetic acid can be confounded by acetate, which occurs naturally in

sediments. All reported concentrations of barium were below the FCV (710 µg/L, based on an average hardness of 158 mg/L as $CaCO_3$). For manganese, the concentrations at most locations exceeded the FCV (790 µg/L at a hardness of 158 mg/L), and the concentrations at two locations, RBSD-12 and RBSD-15, exceeded the FAV (3,400 µg/L at a hardness of 158 mg/L). Similar to iron, the spatial pattern of manganese concentrations appears unrelated to the site, with elevated concentrations observed at reference locations. As shown in Figure 3-2, manganese concentrations were lowest at sample locations immediately adjacent to the area of affected groundwater, with generally higher concentrations occurring downstream. Vanadium was not detected in porewater samples. Acetic acid apparently was not present, as pH levels were neutral to slightly basic in all porewater samples.

Ammonia and sulfide were measured in porewater because they occur naturally in sediments and have the potential to cause toxicity. The national criterion for ammonia in fresh water (USEPA, 1999) is dependent on pH and temperature. Based on an average pH of 7.58 and an average temperature of 21.1°C, the applicable chronic criterion is 2.66 mg/L. All of the porewater ammonia concentrations reported in Table 3-5 are less than or approximately equal to this value and are thus unlikely to cause toxicity. Sulfide was detected only once at a very low concentration.

In summary, the concentrations of most constituents analyzed in whole sediment and porewater were well below screening concentrations. Iron, 3-/4-methylphenol, and manganese are considered further (Section 3.1.3) to determine whether they may have adversely affected benthic macroinvertebrate community quality.

3.1.3 Benthic Macroinvertebrates

The numbers and types of invertebrates collected at each sample location are provided in Appendix C. A total of 142 taxa were identified, including insects (primarily juvenile life stages of flying insects), crustaceans, bivalves, snails, worms, and a jellyfish relative (Table 3-7). The most abundant taxa included mayflies, midges, and clams. Tubificid worms, amphipods, and caddisflies were also abundant at certain locations.

Several metrics were calculated to facilitate the evaluation of benthic community quality. These include basic summary metrics frequently used in ecological assessments, the Hilsenhoff Biotic Index (HBI), and a set of metrics identified by the Ohio Environmental Protection Agency (OEPA) as useful in distinguishing chemical toxicity impacts from other types of impacts.

The summary metrics used in this assessment include:

- Abundance: For wadeable sample locations, this is simply the number organisms. For non-wadeable locations, where the precise sampling area is known, density is calculated as the number of organisms per square meter.

- Taxa richness: This is the number of distinct taxa at each location.

- Diversity: This metric incorporates both taxa richness and the evenness or equitability of allotment of individuals among the taxa, and is calculated using the Shannon-Wiener function (Krebs, 1985):

$$Diversity = -\sum_{i=1}^{t} p_i \times \ln(p_i)$$

where:

t = Number of taxa, and

p_i = Proportion of total sample belonging to the ith taxon.

These metrics are often used to provide a summary of benthic community characteristics, but they are not considered to be highly diagnostic of anthropogenic impacts (e.g., Lydy et al., 2000).

A potentially more diagnostic metric is the HBI, which was originally developed for assessing the level of impact of organic enrichment on riffle zones of Wisconsin streams (Hilsenhoff, 1987). This metric is used by the WDNR and others to assess variety of impact types. It provides a measure of the overall level of tolerance of the taxa present at a given location. Impacted locations are expected to be dominated by tolerant taxa, while intolerant taxa are prevalent at unimpacted locations. Hilsenhoff (1987) developed tolerance ratings for many invertebrate taxa, using a data set of invertebrate community composition in Wisconsin streams affected by varying levels of organic enrichment. The HBI is calculated by multiplying the proportion of the total sample belonging to each taxon by the corresponding tolerance rating:

$$HBI = \sum_{i=1}^{t} p_i \times tolerance\ rating$$

Higher HBI values indicate a higher proportion of tolerant species.

The Biological Response Signature approach, developed by the OEPA, is designed to distinguish impacts due to chemical toxicity from other types of impacts on the benthic community. Yoder and Rankin (1995) compiled a statewide data set of biomonitoring results for benthic invertebrate communities in Ohio. They assigned impact categories to each monitoring location (e.g., complex toxic, channelization, flow alteration, combined sewer outfalls) and examined whether various metrics could be used together to distinguish among the impact types. The following metrics showed a separation between chemical toxicity and other types of impacts (Yoder and Rankin, 1995):

- EPT Taxa Richness: This metric is calculated as the number of mayfly (Ephemeroptera), stonefly (Plecoptera), and caddisfly (Trichoptera) taxa. These three orders of insects are considered sensitive to anthropogenic impacts. Locations classified by OEPA as affected by chemical toxicity supported fewer EPT taxa (usually less than 5 taxa) than other types of impacted locations (Yoder and Rankin, 1995).

- % Mayflies: Mayflies comprised a lower percentage of the total number of organisms at Ohio locations affected by chemical toxicity (usually less than 5%) (Yoder and Rankin, 1995).

- % Tanytarsini Midges: The Tanytarsini tribe of the family Chironomidae (midges) comprised a lower percentage of the organisms at Ohio locations affected by chemical toxicity (usually less than 5%) (Yoder and Rankin, 1995).

- % Diptera (excluding Tanytarsini) + Non-Insects: This metric includes midges other than Tanytarsini, other flies, and non-insects such as worms and mollusks. The percentage of organisms in these categories was higher at Ohio locations affected by chemical toxicity (usually more than 80%) (Yoder and Rankin, 1995).

- % Tolerant: This metric includes several taxa identified by the OEPA as tolerant (DeShon, 1995), including: oligochaete worms, several midge species (*Cricotopus bicinctus*, *Cricotopus sylvestris* group, *Nanocladius distinctus*, *Chironomus* spp., *Polypedilum fallax* group, *Polypedilum illinoense*, and additional species not encountered in this study), and two snail genera (*Ferrissia* and *Physella*). The percentage of organisms classified as tolerant

was higher at Ohio locations affected by chemical toxicity (usually more than 20%) (Yoder and Rankin, 1995).

- % Cricotopus: Midges of the genus *Cricotopus* comprised a higher percentage of organisms at Ohio locations affected by chemical toxicity (usually 5% or more) (Yoder and Rankin, 1995).

The result for any one of these metrics taken alone would not be sufficient to identify an impact type, but taken together they have the potential to discriminate chemical toxicity from other impacts. It is important to note that the biological response signature approach was developed for benthic macroinvertebrates collected using Hester-Dendy samplers in Ohio. The metric values associated with chemical toxicity may be different for different sampling methods and regions. For example, non-insects such as worms and mollusks tend not to colonize Hester-Dendy samplers, and % Diptera + Non-Insect values are therefore likely to be higher for direct sampling methods than for Hester-Dendy samples. For this study, comparisons to the reference locations provide the primary means of evaluating benthic macroinvertebrate community metrics. Survey results are described below for wadeable and non-wadeable sample locations.

3.1.3.1 Wadeable Sample Locations

The benthic macroinvertebrate community metrics for wadeable sample locations in the Menominee River are shown in Table 3-8. The TKN samples are used preferentially for this analysis due to the qualitative nature of the sweep net sampling method. However, the number of species collected using the sweep net method is also presented, because the primary objective of the sweep net sampling was to provide a more comprehensive taxa list for each location.

Comparisons to Reference Locations

The wadeable reference locations (RBM-1, -2, -14, -15) encompassed a range of physical habitat conditions, and differences in metric values among these locations are evident, particularly between upstream and downstream reference locations. Statistical comparisons between study area and reference locations are summarized in Table 3-9. Benthic community metrics for the study area locations were generally within the range of values observed for the reference locations. The HBI score for location RBM-7 was significantly higher than for any of the wadeable reference locations, but no other metric for this location was significantly different from the range of conditions

defined by the reference locations. No other wadeable locations exhibited results that were significantly different than all four reference locations.

The statistical power of these comparisons is summarized in Table 3-10. The ability to detect a difference between locations is dependent upon the variability among replicate samples for each benthic community metric. The HBI and diversity metrics exhibited the least variability and greatest statistical power. The remaining metrics were more variable, such that pairwise statistical comparisons would only detect relatively large differences among locations. Relatively high variability is an inherent feature of benthic macroinvertebrate sampling, but it does not necessarily prevent an understanding of the interactions between benthic populations and their environment (Canton and Chadwick, 1988). To ensure that potential impacts are not overlooked, this assessment also includes an examination of trends in the benthic macroinvertebrate data, in relation to habitat and chemistry results.

Comparisons to Habitat and Chemistry Parameters

The following parameters were considered as variables that might explain the spatial patterns of benthic community metrics:

- Total habitat score,
- Embeddedness score,
- Habitat diversity score,
- Bottom substrate and available cover score,
- River mile,
- Current velocity,
- Water depth,
- Manganese concentration, and
- Iron concentration.

Concentrations of 3-/4-methylphenol were also considered for the two locations where they were detected.

In general, embeddedness and river mile showed the best relationship with the benthic community metrics, and manganese, iron and water depth showed the least relationship. Total habitat also showed a good relationship with some metrics. "Embeddedness" refers to the extent to which gravel, rocks, and debris are covered by deposited silt. As employed in the evaluation of wadeable sampling locations, this habitat metric reflects relatively localized conditions, such as shoreline backwaters

versus riffles. River mile values reflect the large-scale habitat gradient between free-flowing river (near the Ford dam) and impoundment (downstream). Figure 3-3 illustrates embeddedness and total habitat scores; river mile values are provided in Table 2-2.

Spatial patterns in the benthic community summary metrics (i.e., abundance, taxa richness, and diversity) are shown in Figure 3-4. Using non-linear regression as described in Section 2.4, approximately 80% of the variation in these metrics is explained based on physical habitat factors (Figure 3-5; Table 3-11). Abundance is best explained based on total habitat scores. Taxa richness (TKN and sweep net) and diversity are best explained based on the combination of river mile and embeddedness. These metrics decrease with increasing embeddedness of the substrate (i.e., decreasing embeddedness scores) and with progress from upstream to downstream.

Hilsenhoff Biotic Index scores show a very close relationship to embeddedness (Figure 3-6), with 87% of the variation in the HBI explained by embeddedness scores. This relationship is not surprising, given that the HBI was originally developed to assess organic enrichment, which is associated with sediment deposition. The only location which shows a higher (less favorable) HBI score than expected based on embeddedness is RBM-2, a reference location. The HBI score for location RBM-7, which is significantly higher than all four reference locations, is consistent with the very low (unfavorable) embeddedness score for this location.

The biological response signature metrics generally show two types of benthic macroinvertebrate communities (Figures 3-7 and 3-8). Locations having embeddedness scores below 15 (i.e., more embedded substrates) support fewer EPT taxa, fewer mayflies, more diptera and non-insects, and more tolerant organisms than locations with higher embeddedness scores. This finding is consistent with the ecology of depositional areas versus riffles. Embeddedness scores explain approximately 90% of the variation in EPT taxa richness, % mayflies, and % diptera and non-insects. Similar to the HBI, reference location RBM-2 shows the greatest deviation from the values predicted for these metrics based on embeddedness. For % Tanytarsini midges, it was necessary to exclude location RBM-2 (which had an exceptionally high % Tanytarsini value) to develop a successful nonlinear regression model; without this location, river mile and embeddedness scores combine to explain more than 90% of the variation in metric values. Although % tolerant values tended to increase at more embedded locations, embeddedness scores explain less than half the variation in this metric, largely due to the low % tolerant value at the most embedded location (RBM-7). The relative abundance of oligochaete worms strongly influenced % tolerant

values; at RBM-7, oligochaetes were present but were outnumbered by a very high abundance of peaclams. Lastly, % Cricotopus values were very low throughout the study area. Taken together, the biological response signature metrics show a strong link between physical habitat conditions (rather than chemical concentrations) and benthic community composition at wadeable sample locations in the study area.

In addition to the analysis of benthic community metrics, it should be noted that the area of shoreline affected by dam-related water level fluctuations was relatively devoid of macroinvertebrates. In the absence of flow regulation, the shoreline microhabitat would normally be highly utilized by invertebrates. The spatial extent of the affected area was small relative to the size of the river, however. This effect was observed only during sweep net sampling (as TKN sampling was conducted further from shore) and was consistent throughout the study area.

3.1.3.2 Non-Wadeable Sample Locations

In contrast to the wadeable sample locations, the benthic community metrics for non-wadeable locations show a high degree of similarity among locations (Table 3-12; Figures 3-9 and 3-10). The similarity among locations reflects the uniformity of substrate afforded by Hester-Dendy samplers, which tend to diminish the effects of physical habitat conditions. Additionally, depositional sediments were not encountered during sediment sampling efforts at any of the non-wadeable locations, suggesting greater habitat similarity within the river channel than along the shoreline.

No metric values for the non-wadeable study area locations were significantly outside the range of values exhibited by the reference locations (Table 3-13). The statistical power of these comparisons was very good for several metrics, including taxa richness, diversity, HBI, and EPT taxa richness (Table 3-14). Other metrics exhibited lower statistical power, and qualitative trends were therefore examined, as described below.

Highly uniform results were observed for several metrics: number of taxa, diversity, HBI, EPT taxa richness, and % diptera + non-insects. Location RBM-19 exhibited a higher proportion of Tanytarsini midges relative to mayflies than observed at other locations. Both of these taxa are considered sensitive to contaminants, and both were present in abundance at RBM-19, which supported the highest invertebrate density of any sample location. Locations RBM-18, RBM-19, and RBM-22 exhibited somewhat elevated % Cricotopus values; this result is also reflected in the % tolerant scores (which incorporate the Cricotopus species). The % Cricotopus results for these locations were quite variable among replicates, however, and were similar to the results

observed for reference location RBM-16. Taken together, the biological response signature metrics are inconsistent with the biological response signature for chemical toxicity developed by Yoder and Rankin (1995).

Benthic community metric values were also compared with water depth and current velocity measurements, river mile values, and the qualitative instream cover scores developed from the side-scan sonar results. In general, these parameters were not correlated with the biological community metrics. Instream cover scores were strongly correlated with taxa richness, but taxa richness showed so little variation among locations that this correlation probably is not meaningful. Overall, the non-wadeable macroinvertebrate sampling results are best characterized by uniformity among locations and a biological response signature that is not indicative of chemical toxicity.

3.2 Fish Survey

3.2.1 Physical Habitat

Results of the visual-based habitat assessment for Menominee River fish sampling zones are provided in Table 3-15 and illustrated in Figure 3-11. Similar to the habitat assessment results for wadeable macroinvertebrate sampling locations, the habitat metrics that showed the greatest variation among sampling zones included available cover, total embeddedness, and total microhabitat scores. Additionally, sampling zone RBF-5 was observed to contain a high proportion of shallow backwater habitat, which was expected to serve as high-quality "nursery" habitat for numerous small fish.

Water quality measurements and average water depths are shown in Table 3-16. Water quality was generally similar among locations. Water depth exhibited greater variation, with deeper water observed along the Wisconsin shoreline (Figure 3-11).

3.2.2 Fish

Fifteen fish species were collected from the Menominee River area of interest (Table 3-17). The number of individuals and batch weights for each species are listed for each sample location in Table 3-18. The most abundant species were rock bass, smallmouth bass, white sucker, and common shiner. Northern pike and walleye were also important in terms of biomass.

Fish community characteristics were closely related to water depth. The shallower locations along the Michigan shoreline supported more fish of smaller size. Trends in

species richness and diversity paralleled those for fish abundance (Table 3-19, Figure 3-12). Sampling zones RBF-3 and RBF-5, which included the Staff Gauge #2 and seep areas, exhibited the shallowest water depths and the highest fish abundance and diversity. Linear regression analysis showed that average water depth explained between 66% and 81% of the variation in these metrics (Table 3-20, Figure 3-13). This result is consistent with expected fish behavior, as fish tend to move into the shallows at night to forage. Electrofishing is also most efficient in shallow water, but this factor most likely contributed only slightly to the observed results. No correlation was observed between other habitat parameters (visual-based assessment results, water quality) and fish community metrics.

Nearly all fish were visually observed to be plump and healthy in appearance throughout the study area. Gross external anomalies (deformities, eroded fins, lesions, and tumors; DELT) were observed in less than 1% of fish (Figure 3-14). No deformities or tumors were recorded, and the anomalies recorded as lesions generally consisted of apparently fresh lacerations. For comparison, the incidence of DELT anomalies is usually greater than 4% at sites affected by chemical toxicity (Yoder and Rankin, 1995). Intolerant (sensitive) species, including hornyhead chub and mottled sculpin, were observed at nearly all sample locations (Figure 3-14). The only exception was location RBF-8, which contained the deepest water and the fewest fish. Intolerant species are not expected to occur in areas significantly affected by chemical toxicity.

4. Discussion

This section includes (1) a comparison to other biological community surveys of the Menominee River, (2) a biological community quality assessment integrating the results of this and other surveys, and (3) a discussion of the implications of benthic invertebrate and fish community quality for aspects of the Menominee River ecosystem not directly evaluated in this study.

4.1 Comparison to Other Biological Surveys

As part of a study of the effects of flow regulation by dams, the WDNR recently conducted benthic macroinvertebrate (arthropod), mussel, and fish surveys in the Menominee River (WDNR, 1997; 1998; 2000). Sampling was conducted in riverine areas downstream of several dams, including the Ford Dam. Benthic macroinvertebrates were collected in 1996 and 1997 at RM 100.0 near the Wisconsin shoreline (R. Lillie, personal communication), directly opposite RBM-9. Due to

excessive water depth at this location, the benthic macroinvertebrate sampling location in 1998 was moved to an area upstream of RBM-2. Freshwater mussels were surveyed in 1999 along transects spanning the width of the river, approximately at RM 101.3 (upstream of RBM-2) and RM 100.6 (near RBM-3) (R. Piette, personal communication). Fish were surveyed in 1996 and 1997 over a one-mile stretch of river between RM 99.9 and RM 100.9 (WDNR, 1998), which encompasses RBF-1 through RBF-6.

In 1996, benthic macroinvertebrates collected from RM 100.0 (near RBM-9) using both kicknet and microhabitat sampling (hand-picking) included 25 taxa, 15 EPT taxa, and 85% mayflies (WDNR, 1998). Samples collected in 1997 included approximately 60% mayflies (WDNR, 1998) and 24 EPT taxa (R. Lillie, personal communication). Due to the use of somewhat different sampling methods (i.e., different sampling equipment, EPT taxa summed rather than averaged over multiple samples), these results are not directly comparable to the results of the current study. However, they indicate that benthic macroinvertebrate community composition at the sample location was similar to that observed in 2000 at other locations having relatively low embeddedness (where TKN samples typically contained 60% mayflies and 13 EPT taxa; Figure 3-8). The WDNR's results also indicate similar benthic macroinvertebrate communities at sampling locations elsewhere in the Menominee River (WDNR, 1998).

In addition to qualitative data on freshwater mussels collected in conjunction with arthropod sampling, the WDNR conducted a quantitative mussel survey in 1999 using snorkeling and SCUBA. The transect located at RM 100.6 (near RBM-3) supported the highest number of freshwater mussel species of any survey location in the Menominee River (WDNR, 2000). At all sample locations, mussels were found to be most abundant at an intermediate distance between the shoreline and the river channel. This atypical distribution pattern was attributed to the combined dam-related impacts of nearshore water level fluctuation and very low embeddedness (termed sediment armoring) in the channel (WDNR, 2000). The relatively low abundance of mussels near the shoreline may account for the low diversity of freshwater mussels encountered throughout the study area in the current study.

Fish community composition in 1996 and 1997 (WDNR, 1998) was very similar to that observed in 2000. A total of 15 species were observed, and diversity (Shannon-Wiener) was reported as 2.1 and 2.0 in 1996 and 1997, respectively (WDNR, 1998). Species richness downstream of the Ford dam was similar to that observed throughout the upper portion of the Menominee River but lower than observed in the lower river. This difference was attributed to current and historical barriers to fish dispersal, in the

form of dams and waterfalls (WDNR, 1998). Smallmouth bass growth was also evaluated and was found to vary relatively little among study sites (WDNR, 1998). Similar to the current study, visual-based habitat assessment results did not explain variations in fish abundance and distribution (WDNR, 1998); the WDNR did not directly evaluate the effects of water depth.

4.2 Biological Community Quality Assessment for Macroinvertebrates and Fish

Biological community survey results provide no evidence of adverse impacts related to groundwater migrating from the Ford/Kingsford site. This assessment is based on the following findings:

- Biological community metrics within the study area are similar to those at reference locations that have similar habitat characteristics;
- Biological community metrics are generally closely correlated with physical habitat characteristics and are not correlated with chemical concentrations;
- Sample locations immediately adjacent to the area of affected groundwater do not deviate from the biological community characteristics that are predicted based on habitat conditions; and
- These results are consistent with biological survey data collected by WDNR from additional study area locations during 1996-1999.

These findings are based on an extensive sampling effort, such that any impact occurring at an ecologically relevant scale would have been detected. The sampling locations included anticipated "hot spots" of groundwater upwelling (i.e., the Staff Gauge #2 and seep areas). Subsurface temperature data confirm that groundwater upwelling was occurring at some of the sample locations, and the detection of 3-/4-methylphenol indicates that some of the upwelling groundwater may have originated in the affected portion of the groundwater system. Thus, it is reasonable to conclude that mechanisms such as degradation and dilution effectively detoxify the groundwater before it contacts the benthic macroinvertebrate and fish communities.

The apparent lack of chemical toxicity is observed even at locations where chemical concentrations in sediment porewater are measured or estimated as exceeding the MDEQ's water quality values. This result reflects the highly conservative nature of the water quality values for 3-methylphenol and manganese. These values were developed

using "Tier II" methods, whereby uncertainty factors are used to compensate for limited toxicity data availability. The uncertainty factors are intended to be overconservative in most cases. Although toxicity data are limited for 3-methylphenol, more extensive data are available for other methylated phenols, particularly phenol and 2,4-dimethylphenol. Numerous studies of quantitative structure-activity relationships indicate that the toxicity of monomethylated phenols is intermediate between phenol and dimethylated phenols (e.g., Feng et al., 1996; Karabunarliev et al., 1996; Schultz et al., 1986). The FCVs for phenol and 2,4-dimethylphenol are higher than the 3-/4-methylphenol concentrations estimated in sediment porewater from the Menominee River. Thus, the aquatic toxicity literature indicates that the estimated exceedance of the FCV for 3-methylphenol reflects an overconservative water quality value rather than a real potential for toxicity.

Manganese can occur naturally at toxic concentrations in anoxic sediment porewater (Lasier et al., 2000). Indeed, the manganese concentrations in Menominee River porewater appear to be naturally occurring, based on the high concentrations at reference locations. Several factors may contribute to the lack of apparent toxicity at the observed concentrations: (1) the FAV and FCV incorporate a Tier II uncertainty factor to compensate for limited data availability, resulting in water quality values that are probably overconservative; (2) the water quality values are protective of the species that are most sensitive to manganese (salmonids), which do not occur in the Menominee River study area; and (3) species that live in very close contact with sediment are relatively tolerant of constituents (such as manganese) that are normally present at higher concentrations in sediment porewater than in surface water.

4.3 Implications for Other Ecosystem Components

The high quality of the benthic macroinvertebrate and fish communities in the Menominee River study area has implications for other components of the ecosystem, including aquatic-feeding wildlife and instream microfauna. A variety of birds and mammals are expected to feed on aquatic organisms in the Menominee River. For example, bird species observed during sampling activities included bald eagles (which feed on fish) and Eastern kingbirds (which feed on flying insects such as adult midges and mayflies). Mammals such as mink and raccoons most likely feed on fish and invertebrates in the area as well. These species' success depends on the availability of aquatic prey. Although shoreline feeders might be affected by water level fluctuation and the resulting non-use of the shoreline by invertebrates, the river overall contains an abundance of aquatic prey. Based on the non-bioaccumulative nature of the chemicals

occurring in groundwater, aquatic prey obtained from the Menominee River are expected to provide a healthy food base for wildlife in the area.

At the opposite end of the food chain, organisms inhabiting the transition zone between groundwater and surface water have recently been a focus of attention (USEPA, 2000b). These organisms include microfauna such as bacteria, and in some cases meiofauna such as small, highly adapted amphipods (Boulton et al., 1998). USEPA (2000b) summarizes the functions of the transition zone as follows:

- High quality habitat: Areas of groundwater upwelling and downwelling can have important habitat functions due to the temperature differential between groundwater and surface water, as well as nutrient inputs.
    - Although not applicable to the coolwater Menominee River fish community, coldwater fish species such as salmonids often rely on upwelling groundwater for temperature regulation.
    - Conversely, upwelling groundwater areas can provide a warm refuge for aquatic organisms during winter.
    - Upwelling groundwater often enhances the growth of macrophytes.
    - Downwelling zones provide a refuge for macroinvertebrates (e.g., during spates).

- Contaminant attenuation/removal: Strong redox gradients in the transition zone enhance biogeochemical activity and microbial processes. As a result, a variety of contaminants and nutrients can be degraded or removed from groundwater within the transition zone.

- Nutrient and carbon cycling: Enhanced microbial activity also results in very active nutrient and carbon cycling.

- Food base for benthic organisms: Microbial biomass can serve as the base of a detrital food chain that can be important to overall ecosystem productivity.

A functioning transition zone is thus important to the quality of macroinvertebrate and fish communities. If the functions of the transition zone were significantly impaired, the quality of macroinvertebrate and fish communities would decline. Because the macroinvertebrate and fish communities in the Menominee River study area show no evidence of adverse effects related to migrating groundwater, it is apparent that the important functions of the transition zone are not significantly impaired.

5. Conclusions

Based on macroinvertebrate and fish surveys of the Menominee River near Kingsford, Michigan, there is no evidence that groundwater migrating from the Ford/Kingsford site is adversely affecting the aquatic ecosystem. This conclusion is based on the following findings:

- Direct substrate sampling of benthic macroinvertebrates shows a very close relationship between physical habitat conditions and benthic community composition. Conversely, there is no correlation between chemical concentrations or proximity to the site and biological community metrics.

- Artificial substrate sampling, which controls for physical habitat differences, shows a high degree of uniformity in benthic community composition throughout the study area.

- Sensitive macroinvertebrates such as mayflies, stoneflies, caddisflies, and Tanytarsini midges were collected at all macroinvertebrate sampling locations.

- Fish community composition was strongly influenced by water depth, not by proximity to the site. Sampling zones immediately adjacent to the site exhibited the highest fish abundance and diversity.

- Sensitive fish species, including hornyhead chub and mottled sculpin, occurred throughout the study area.

- Fish throughout the study area were observed to be plump and healthy, with very few external anomalies. This observation is consistent with the WDNR's finding that smallmouth bass growth in the study area was similar to that observed elsewhere in the Menominee River.

- The high quality of the benthic macroinvertebrate and fish communities indicates that important ecological functions of the transition zone between groundwater and surface water are not significantly impaired.

Table 2-4. Visual-Based Habitat Assessment Protocol (GLEAS 51)

Habitat Parameter	Excellent	Good	Fair	Poor
Substrate and Available Cover				
Bottom Substrate Available Cover	Greater than 50% rubble, gravel, submerged logs, undercut banks, or other stable habitat.	30-50% rubble, gravel, or other stable habitat Adequate habitat	10-30% rubble, gravel or other stable habitat. Habitat availability less than desirable.	Less than 10% rubble, gravel or other stable habitat. Lack of habitat is obvious.
	16-20	11-15	6-10	0-5
Embeddedness/Siltation	Gravel, logs, cobble, and boulder particles have between 0 and 25% of their surface covered by find sediment/silt.	Gravel, logs, cobble, and boulder particles have between 25 and 50% of their surface covered by fine sediment/silt.	Gravel, logs, cobble and boulder particles have between 50 and 75% of their surface covered by fine sediment/silt.	Gravel, logs, cobble, and boulder particles have over 75% of their surface covered by fine sediment/silt.
	16-20	11-15	6-10	0-5
Velocity:Depth Pool - 1 ft/s 1.5ft Shallow Pool - 1 ft/s 1.5 ft Run - 1 ft/s 1.5 ft Riffle - 1 ft/s 1.5 ft	All habitats well represented. None greater than 50% of total area.	Only 3 of the 4 habitat categories present. Or if all 4 are present with one greater than 50% of total area.	Only 2 of the 4 habitat categories present.	Dominated by one velocity/depth category (usually pool).
	16-20	11-15	6-10	0-5

Table 2-4. Visual-Based Habitat Assessment Protocol (GLEAS 51)

Habitat Parameter	Excellent	Good	Fair	Poor
Channel Morphology				
Flow Stability	Continual flow all year. Natural water supply substantial.	Seasonal high flows. Low flow constant or nearly so. Some point discharge contributes to flow.	Periodic high and low flows. Irregular flow pattern. Discharges contribute substantially to low flow.	Ephemeral stream. Usually no mid-summer flow. If it flows year-round, discharge form major contribution.
	12-15	9-11	4-7	0-3
Bottom Deposition/ Sedimentation	Less than 5% of the bottom affected by deposition. Hard bottom substrate.	5-30% affected. Some deposition in pools. Soft bottom from sediments mainly in pools.	30-50% affected. Deposits, obstructions, constrictions, and bends. Some filling of pools with sediments/sand. Soft bottom more common.	More than 50% of the bottom affected. Pool almost absent due to deposition. Only large rocks in riffle expos. Frequent soft bottom, loose deposits very common, often deep.
	12-15	6-11	4-7	0-3
Pools-Riffles-Runs-Bends	Variety of habitats. Deep riffles and pools.	Adequate depth in pools and riffles. Bends provide habitat.	Occasional riffle or bend. Bottom contours provide some habitat.	Essentially a straight stream. Generally all falt water or shallow riffle. Poor habitat.
	12-15	9-11	4-7	0-3

Table 2-4. Visual-Based Habitat Assessment Protocol (GLEAS 51)

Habitat Parameter	Excellent	Good	Fair	Poor
Riparian and Bank Structure				
Bank Stability	Stable. No evidence of erosion or bank failure. Side slopes generally 30% potential for future problem.	Moderately stable. Infrequent, small areas or erosion mostly healed over. Side slopes up to 40% on one bank. Slight potential in extreme floods.	Moderately unstable. Moderate frequency and size of erosional areas. Side slopes up to 60% on some banks. High erosion potential during extreme high flow.	Unstable. Many eroded areas. Side slopes common. "Raw" areas frequent along straight sections and bends.
	9-10	6-8	3-5	0-2
Bank Vegetative Stability	Over 80% of the streambank surfaces covered by vegetation or boulders and cobble.	50-79% of the streambank surfaces covered by vegetation, gravel or larger material.	25-49% of the streambank surfaces covered by vegetation, gravel or larger material.	Less than 25% of the streambank surfaces covered by vegetation, gravel or larger material.
	9-10	6-8	3-5	0-2
Streamside Cover	Dominant vegetation is shrub.	Dominant vegetation is of tree form.	Dominant vegetation is grass or forbes.	Over 50% of the streambank has no vegetation and dominant material is soil, rock, bridge materials, culverts, mine trailings.
	9-10	6-8	3-5	0-2

Table 2-5. Summary of Sediment Chemistry Analyses

Sample Matrix	Parameter	Method
Sediment	Phenolic compounds (phenol, monomethylphenols, and dimethylphenols)	8270C
Sediment	Total organic carbon	9060
Sediment	Moisture	Gravimetric

[b]Not available (sampling zone outside of bathymetry survey area).

Table 3-17. Fish Species Collected From the Menominee River Study Area

Family	Scientific Name	Common Name	Description[a]	Trophic[b]	Tolerance[b]
Esocidae	Esox Lucius	Northern Pike	Widely distributed in glaciated areas. Inhabits cool to moderately warm weedy lakes and sluggish rivers with quiet pools to fast currents over sand and mud.	P	M
Cyprinidae	Nocomis biguttatus	Hornyhead Chub	Appears to be decreasing over its general range, possibly due to siltation and intermittent flow. Common in clear water, riffles and pools over gravel or rubble in medium sized rivers.	S	I
	Nocomis raneyi	Golden Shiner	Found in sloughs and pools, clear water over sand with heavy vegetation. Medium to large rivers. Omnivore (algae and plants, crustaceans, terrestrial insects).	O	T
	Notropis cornutus	Common Shiner	Inhabits small, moderately clear streams over gravel, rubble and bedrock pools. Generalized food habits, primarily aquatic and terrestrial insects.	S	M
Catostomidae	Catomus commersoni	White Sucker	Common in most streams, clear to slightly turbid water over gravel and sand. Benthic invertebrate feeder.	O	T
Centrarchidae	Ambloplites rupestris	Rock Bass	Prefers clear, cool to warm waters over gravel or rock with some vegetation or cover. Feed on immature aquatic insects, small minnows, crayfish.	P	M
	Lepomis macrochirus	Bluegill	Occurs in clear water over sand and gravel. Intolerant of continuous high turbidity and siltation and thrives in warm waters where vegetation and cover is present. Generalized invertebrate feeder.	S	M
	Micropterus dolomieui	Smallmouth Bass	Common in medium to large rivers,moderate to swift currents. Abundance is decreasing and fishing along Great Lakes shoreline is no longer excellent. Prefers clear, flowing streams over rocks and sand, seeks out rocky ledges or weedy shorelines. Smallmouth is the ecological replacement for the spotted bass and the largemouth bass in clear,cool, permanent-flowing streams. It has low tolerance for siltation and turbidity. Piscivore (including larger invertebrates).	P	M
	Micropterus salmoides	Largemouth Bass	Widely distributed, abundant in medium to large rivers, clear to slightly turbid water over sand and gravel. Intolerant of excessive turbididty and siltation and thrives in warm waters having no noticeable current. Piscivore (including larger invertebrates).	P	M
	Pomoxis nigromaculatus	Black Crappie	Occurs in clear to slightly turbid water over sand and abundant cover in the form of submerged timber or aquatic vegetation. Intolerant of turbidity and siltation. Piscivore (including invertebrates).	P	M
Percidae	Etheostoma nigrum	Johnny Darter	Widely distributed, more abundant in creeks, tolerant of turbidity but avoids streams that are excessively turbid and silty and those with high gradients or continuous strong flow. Often found in quiet pools over sand. General invertebrate feeder.	S	M
	Perca flavescens	Yellow Perch	Panfish. Adaptable to a wide variety of habitats. Prefers sloughs with modest amounts of vegetaion and water of moderate fertility, clear to slightly turbid water over sand. Generalized invertebrate feeder.	S	M
	Percina caproides	Log Perch	Common in medium to large rivers with diverse habitats (pools) and clear water over sand and gravel. Generalized invertebrate feeder.	S	M
	Stizostedion vitreum	Walleye	Common in large rivers, clear water over sand, gravel, mud.	P	M
Cottidae	Cottus bardi	Mottled Sculpin	Common in cold headwater streams in clear to slightly turbid water over sand and gravel. Found in pools and in riffles in the vicinity of vegetation or debris. Distribution is dependent on shelter. Diet consists of larval aquatic insects and an occasional small fish (benthivore).	S	I

[a]Adapted from Becker (1983).

[b]Trophic guilds and tolerance ratings are from Barbour et al. (1999):

P - Piscivore
H - Herbivore
O - Omnivore
S - Insectivore
F - Filter Feeder
G - Generalist Feeder
V - Invertivore
I - Intolerant
M - Intermediate Tolerance
T - Tolerant

a. Percentage of fish exhibiting external anomalies (deformities, eroded fins, lesions, or tumors).
b. Percentage of fish classified as intolerant (sensitive).

Appendix A

Groundwater Toxicity Test and Toxicity Identification Evaluation (TIE) Results

Appendix A: Groundwater Toxicity Test and Toxicity Identification Evaluation (TIE) Results

At the request of the MDEQ, ARCADIS Geraghty & Miller conducted toxicity testing and chemical analyses of groundwater samples collected from wells located near the Menominee River. The tests were conducted using standard methods developed for whole-effluent toxicity (WET) testing. Limited additional testing was conducted directly by the MDEQ. A total of 78 toxicity tests were conducted, encompassing two test species (fathead minnows and *Daphnia magna*), 22 groundwater wells, and two seep locations. Standard Toxicity Identification Evaluation (TIE) procedures were conducted for seven water samples (six groundwater and one seep) to facilitate the identification of chemicals contributing to toxicity. Complete toxicity test and TIE results are provided by AScI (1999; 2000a,b) and New England Bioassay (2000a-e). As described in Section 1 of this report, groundwater toxicity test results are not necessarily predictive of ecological conditions in the Menominee River. Rather, these tests provide a means of focusing further evaluations designed to assess potential impacts on aquatic life (e.g., the bioassessment described in this report).

Toxicity Test Results

Toxicity test results are summarized in Table A-1. The test results are summarized as toxic unit (TU) values, which correspond to the amount of dilution with clean laboratory water that is required to achieve a specified level of test organism response. Acute TU (TU_A) values are based on a specified response of 50% mortality. A TU_A less than 1.0 indicates less than 50% mortality in the undiluted sample and is viewed by MDEQ as acceptable for discharge to surface waters. For certain samples, TU values were also calculated for 50% *Daphnia magna* immobilization (where this response was observed). Daphnid immobilization is considered equivalent to mortality for the purpose of calculating acute water quality criteria (Stephan et al., 1985).

Split sampling and/or repeated toxicity testing were implemented for nine groundwater wells and one seep location. The TU values varied considerably among tests, and in several cases the classification of samples as toxic (TU > 1.0) or nontoxic (TU < 1.0) varied among tests. One factor contributing to the observed variation was likely a difference in test procedures between laboratories. Specifically, New England Bioassay acclimated the *Daphnia magna* test organisms to very hard water conditions prior to toxicity testing, per USEPA guidance (USEPA, 1993), whereas AScI Corporation omitted this procedure. Test organism acclimation reduces stress related to water hardness and provides a result that is more indicative of the toxicity of

constituents of interest in the water sample. Additionally, variability and false positives are recognized as one of the limitations of WET test procedures (Warren-Hicks et al., 2000; Moore et al., 2000a; Moore et al., 2000b).

Table A-2 summarizes the spatial relationship between the tested groundwater wells and the Menominee River. A comparison of Tables A-1 and A-2 supports the following conclusions:

- Groundwater samples collected to the northwest of GM-5 and to the southwest of GM-27 did not consistently exhibit toxicity (TU > 1.0);
- Seven of twelve groundwater wells and one of two seeps between GM-5 and GM-27 exhibited toxicity (TU > 1.0);
- Groundwater collected from GM-25B and co-located extraction well GM-EW3 required between five and sixteen-fold dilution to achieve less than 50% mortality; and
- Dilution of approximately two-fold or less was generally sufficient to achieve less than 50% mortality for the remaining toxic samples.

TIE Results

The identity of chemicals contributing to groundwater toxicity was investigated using standard USEPA methods for a "Phase I" TIE, which, which involve specific manipulations of the sample, designed to remove toxicity due to certain classes of chemicals. Initially, a TIE was conducted for GM-25B groundwater using more than 20 different sample manipulations. The procedures which lowered toxicity in GM-25B groundwater included solid phase extraction with a C18 column, indicating a contribution to toxicity due to hydrophobic organic chemicals, and addition of EDTA, indicating a contribution to toxicity due to metals. Subsequent TIE testing was limited to these procedures.[1] The results of the TIE tests are summarized in Table A-3.

In most cases, the TIE results indicated toxicity due to a combination of hydrophobic organic chemicals and metals. However, the treatments which achieved a TU_A less

[1] An ion exchange procedure was also implemented for seep sample SP-2; results were inconclusive.

than 1.0 did not completely eliminate toxicity in most cases. Combined removal of organic compounds and addition of EDTA generally resulted in survival of 60-80% for both test species. The TIE results do not distinguish whether incomplete removal of metal toxicity or an uncharacterized source of toxicity (such as major ions; see below) was responsible for the residual toxicity. Removal of hydrophobic organic compounds was believed to be essentially complete, based on the use of a large volume of sorbent in the C18 column.

Procedures that did not reduce toxicity in the GM-25B TIE are also of interest, as they indicate classes of chemicals that were not important contributors to the observed toxicity. For example, toxicity due to particulate material was suspected in samples where a precipitate was evident; however, filtration did not reduce toxicity. Aeration also did not reduce toxicity, indicating that volatile compounds were not important contributors to toxicity.

Identification of Toxicants

Based on the TIE results, the classes of chemicals contributing to observed groundwater toxicity were identified as hydrophobic organic compounds, metals, and potentially an additional class of chemicals not affected by the TIE procedures. The analytical chemistry results for the TIE samples were examined to more specifically identify the apparent toxicants. The details of this evaluation are provided by ARCADIS Geraghty & Miller (2000). Three groups of chemicals were identified as contributors to toxicity: phenolic compounds, iron, and major ions, as described below.

Phenolic Compounds: The only hydrophobic organic compound that was consistently detected in the TIE samples was 2,4-dimethylphenol. Monomethylphenols and phenol were also detected in certain samples. Although the concentrations of these chemicals by themselves were not sufficient to cause toxicity in most of the TIE samples (Tables A-4 and A-5), phenolic compounds may have contributed to toxicity as part of a chemical mixture, together with iron and major ions.

Iron: In the TIE samples, detected metal concentrations were generally well below the MDEQ's Final Acute Values (FAVs), despite the TIE results indicating toxicity due to metals. However, the MDEQ has not developed an FAV for iron. Aquatic toxicity values for iron are available from the USEPA's AQUIRE database (Table A-6). Iron concentrations in all TIE samples except

SP-2 were within the range of LC50s reported for *Daphnia magna* and other species (Table A-4).

Major Ions: In fresh water, the major ions which constitute total dissolved solids are typically calcium, potassium, magnesium, sodium, chloride, bicarbonate, and sulfate. The standard TIE procedures implemented as part of this investigation do not directly address major ion toxicity. However, toxicity due to major ions can be predicted using the Gas Research Institute's Freshwater Salinity Toxicity Relationship (FW STR) model (Tietge et al., 1994), which was developed based on the results of toxicity tests with over 2,900 ion solutions. Validation studies have indicated that the model is somewhat over-predictive of toxicity for fathead minnows and *Daphnia magna* (Mount et al., 1997). The FW STR model predicts all of the TIE samples to be toxic to both test species due to major ions alone (Table A-7). Bicarbonate was the most important of the major ions in contributing to toxicity, based on a comparison to single-salt and double-salt toxicity test results (Mount et al., 1997) as well as model simulations. Bicarbonate may account for the residual toxicity observed following organic compound removal and EDTA addition in the TIE.

In groundwater samples that were tested for toxicity but not evaluated using TIE procedures, the relationship between toxicity and chemistry was consistent with the identification of toxicants described above. Chemistry results for the toxicity test samples are provided in the draft Remedial Investigation Report (ARCADIS Geraghty & Miller, 2001). Overall, the concentrations of phenolic compounds, major ions, and iron exhibited a strong correlation with toxicity.

Application to Menominee River Bioassessment

The results of the groundwater toxicity investigation were used to focus the Menominee River bioassessment study. The spatial extent of groundwater toxicity provided a basis for selecting study area and reference sample locations in the river. The identification of groundwater toxicants provided a basis for selecting a limited set of target analytes for sediment and porewater analyses. The chemical concentrations associated with toxicity in the groundwater toxicity tests also provide a means of evaluating concentrations occurring in sediment porewater. In the bioassessment study, all concentrations of chemicals of interest occurring in sediment porewater were well below levels associated with toxicity (see Section 3 of this report). This finding is consistent with the high quality of the benthic macroinvertebrates and fish communities observed in the Menominee River study area.

[a]For comparison, the elevation of the Menominee River bed ranges from 1016 to 1036 ft.

Table A-3. TIE Procedures that Removed Toxicity from Groundwater or Seep Samples[a]

	GM-5 11/30/99	GM-25A 12/1/99	GM-25B 10/20/99	GM-26A 11/29/99	GM26C 11/30/99	GM-27A 12/1/99	SP-2[b] 6/27/00
Daphnia magna							
C18 column					X		
EDTA							X
C18 + EDTA	X	X	X	X		X	
Residual toxicity	X	X	X	X	X	X	
Fathead minnow							
C18 column			X				
EDTA							
C18 + EDTA	X	X		X	X	X	
Residual toxicity	X	X		X	X	X	

a. Removal of toxicity by sample passage through a C18 column indicates toxicity due to hydrophobic organic compounds. Removal of toxicity by EDTA addition indicates metal toxicity. Residual toxicity indicates either toxicity due to other factors (e.g., major ions) or incomplete removal of metal toxicity. Incomplete removal of organic toxicity was unlikely based on use of a large volume of sorbent.

b. Seep sample SP-2 was not toxic to fathead minnows and was only marginally toxic to *Daphnia magna* (TIE results interpreted based on behavioral endpoints due to high survival).

Table A-4. Concentrations of Phenolic Compounds and Iron in TIE Samples[a]

	GM-5	GM-25A	GM-25B	GM-26A	GM-26C	GM-27A	SP-2
2,4-Dimethylphenol	900	900	3,900	850	2200	890	590
2-Methylphenol	<20	<20	4,800	<20	<50	<20	<5
3-Methylphenol/4-Methylphenol	<20	<20	13,000	350	<50	<20	<5
Phenol	<20	<20	8,000	<20	<50	<20	<5
Iron	11,000	28,000	120,000	24,000	8,100	36,000	260

a Units are µg/L.

Table A-5. Aquatic Toxicity Values for Phenolic Compounds[a]

Chemical	Species Mean Acute Value		Final Acute Value
	Fathead Minnow	*Daphnia magna*	
2,4-Dimethylphenol	17,000	4,800	2,700
2-Methylphenol	14,000	12,000	1,500
4-Methylphenol	16,500	15,000	570
Phenol	29,500	12,600	3,200

a Values are as listed in MDEQ's Rule 57 Aquatic Values Data Sheets. Species Mean Acute Values represent the geometric mean of LC50s for each species.

Table A-6. Acute Toxicity of Iron to Aquatic Species[a]

Latin name	Common name	Duration (days)	LC50 or EC50[b] (µg/L)	Reference
Asellus aquaticus	Aquatic sowbug	4.00	124,000	Martin and Holdich, 1986
Austropotamobius pallipes pallipes	Crayfish	4.00	18,500	Boutet and Chaisemartin, 1973
Crangonyx pseudogracilis	Amphipod	4.00	120,000	Martin and Holdich, 1986
Daphnia magna	Water flea	2.00	9,600	Biesinger and Christensen, 1972
Daphnia magna	Water flea	2.00	76,000	Cabejszek and Stasiak, 1960
Daphnia magna	Water flea	2.00	8,600	Belabed et al., 1994
Daphnia magna	Water flea	2.00	12,000	Belabed et al., 1994
Daphnia magna	Water flea	2.00	6,400	Belabed et al., 1994
Daphnia magna	Water flea	2.00	13,000	Belabed et al., 1994
Daphnia pulex	Water flea	2.00	9,000	Lee, 1976
Daphnia pulex	Water flea	2.00	2,800	Lee, 1976
Diaptomus forbesi	Calanoid copepod	2.00	86,500	Mullick and Konar, 1991
Gambusia affinis	Western mosquitofish	4.00	26,000	Wallen et al., 1957
Ictalurus punctatus	Channel catfish	4.00	>500,000	Clemens and Sneed, 1959
Morone saxatilis	Striped bass	4.00	4,000	Hughes, 1973
Morone saxatilis	Striped bass	4.00	6,000	Hughes, 1973
Orconectes limosus	Crayfish	4.00	32,000	Boutet and Chaisemartin, 1973
Tubifex tubifex	Tubificid worm	4.00	101,840	Khangarot, 1991

a Data obtained from U.S. EPA's AQUIRE database.

b Concentration associated with 50% mortality (LC50) or 50% mortality + immobilization (EC50).

Table A-7. Major Ion Toxicity in TIE Samples Predicted by the Freshwater Salinity Toxicity Relationship Model

Sample	GM-5	GM-25A	GM-25B	GM-26A	GM-26C	GM-27A	SP-2
Calcium (mg/L)	110	170	740	160	130	210	160
Magnesium (mg/L)	170	230	570	160	160	180	130
Potassium (mg/L)	6.2	6.3	15	4.4	6.8	5.1	4.6
Sodium (mg/L)	34	24	57	20	46	18	13
Chloride (mg/L)[a]	17	11	36	19	19	16	12
Alkalinity (mg/L as $CaCO_3$)[b]	1040	1520	2292	1010	1050	1370	890
Bicarbonate (mg/L)[c]	1268	1853	2794	1231	1280	1670	1085
Sulfate (mg/L)[a]	9	29	17	10	<5	5.2	<5
Charge balance	-1.57%	-8.11%	+59.05%[d]	+1.91%	+1.11%	-6.40%	+6.34%
Predicted LC50, Fathead minnow	76%	52%	33%	78%	75%	58%	89%
Predicted LC50, *Daphnia magna*	81%	56%	34%	84%	81%	64%	96%
Predicted TU_A, Fathead minnow	1.3	1.9	3.0	1.3	1.3	1.7	1.1
Predicted TU_A, Daphnia magna	1.2	1.8	2.9	1.2	1.2	1.6	1

a Measured for TIE sample SP-2 only; for other samples, estimated as the average of concentrations previously reported for the same well boring.

b Average of initial and renewal sample results reported by the toxicity testing laboratory.

c Bicarbonate concentration (mg/L as HCO_3) calculated by STR model from alkalinity (mg/L as $CaCO_3$).

d Remainder of charge balance attributable to acetate ions (acetic acid), hydrogen ions, and iron.

Table 3-20. Equations Relating Fish Community Metrics and Water Depth

y	x	equation	r^2
Number of Fish	Depth	y = 19.3x + 4.70	71%
Number of Species	Depth	y = -0.95x + 14.80	81%
Diversity	Depth	y = -0.11x + 2.15	66%
Average Biomass	Depth	y = -49.9x + 350	74%

[a]Sample depth was not measured during the Hester-Dendy deployment

[b]NR = Sample not retrievable

[c]Sample was poorly preserved and therefore was not processed

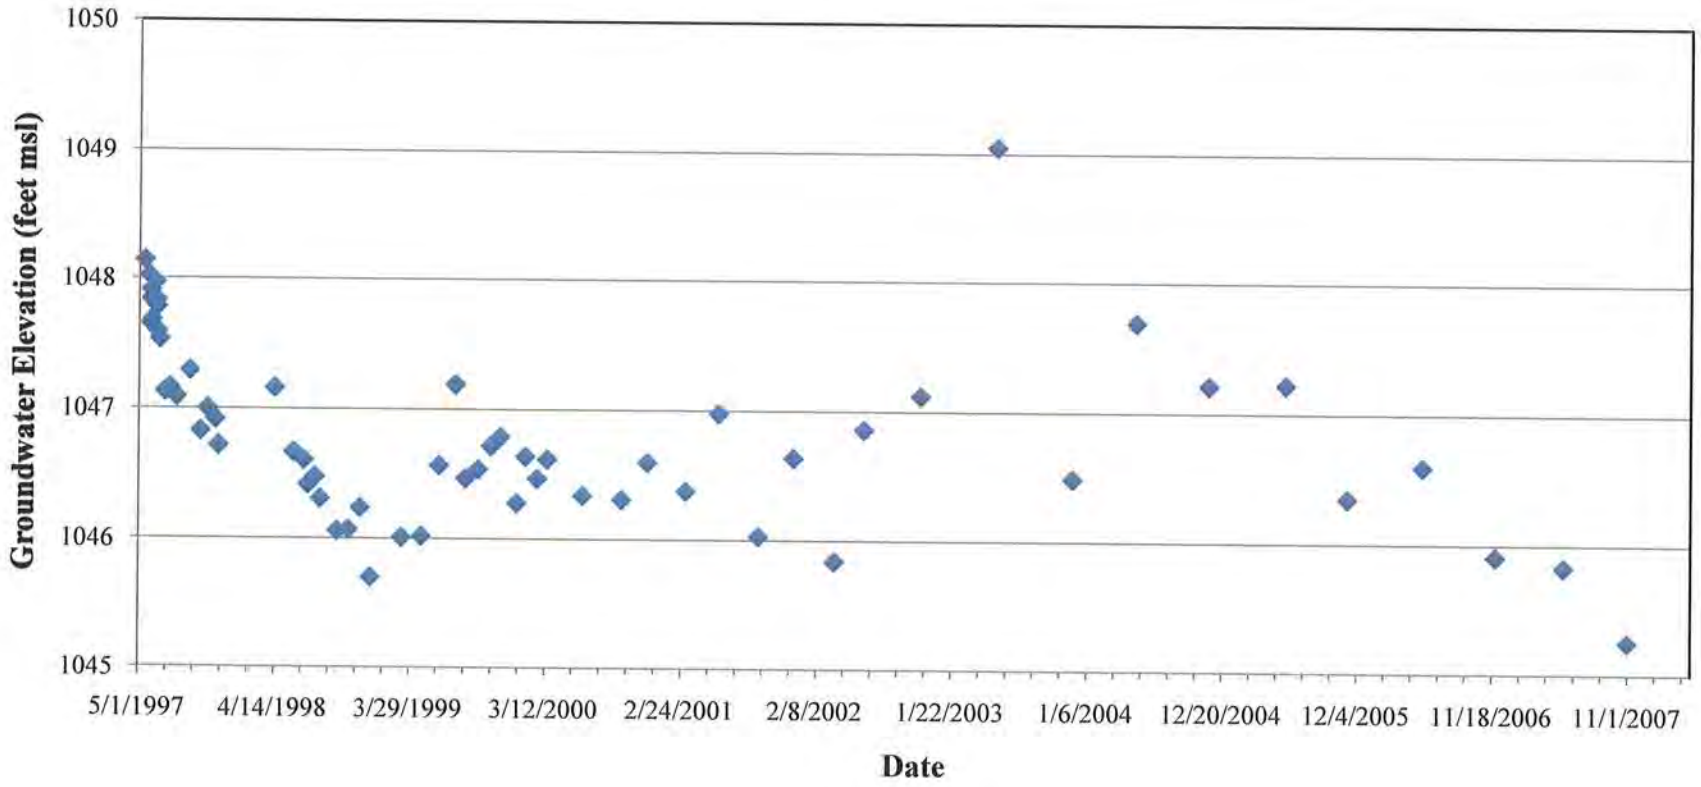
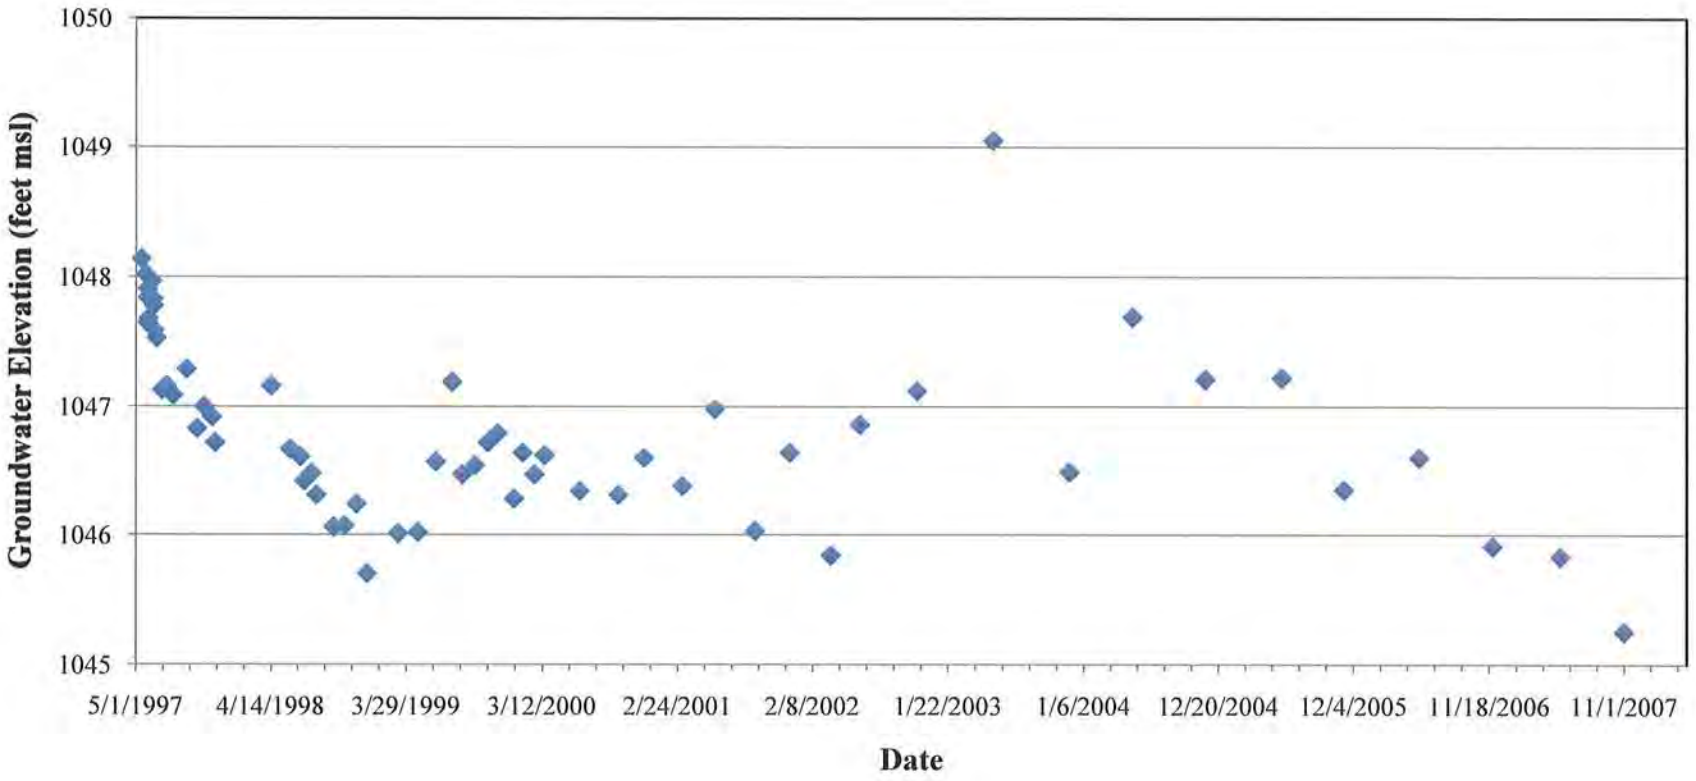
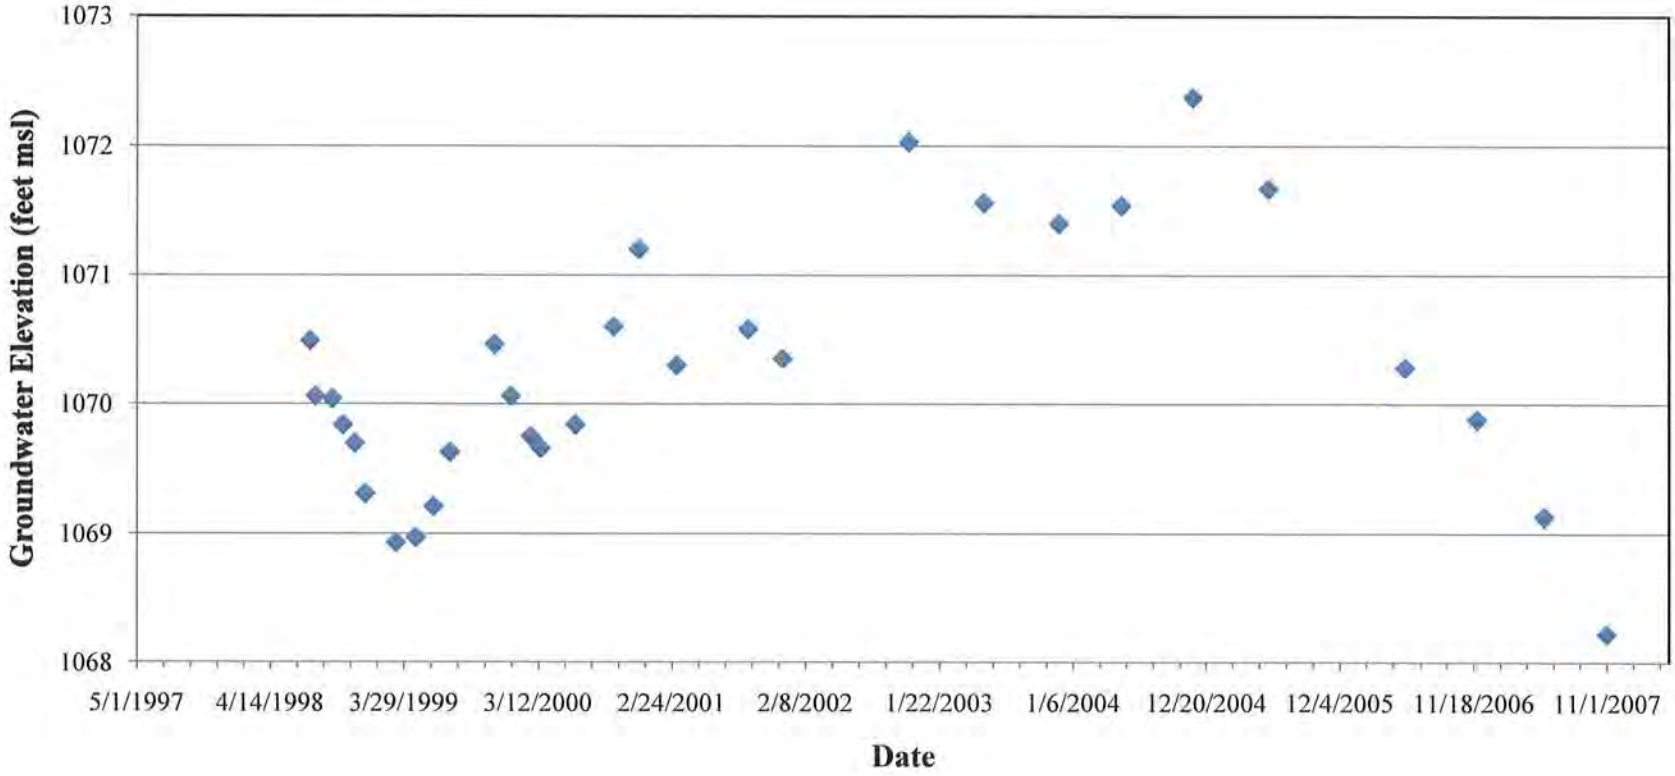
Groundwater Elevations in Well GM-2B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 271-281 Feet Below Ground Surface



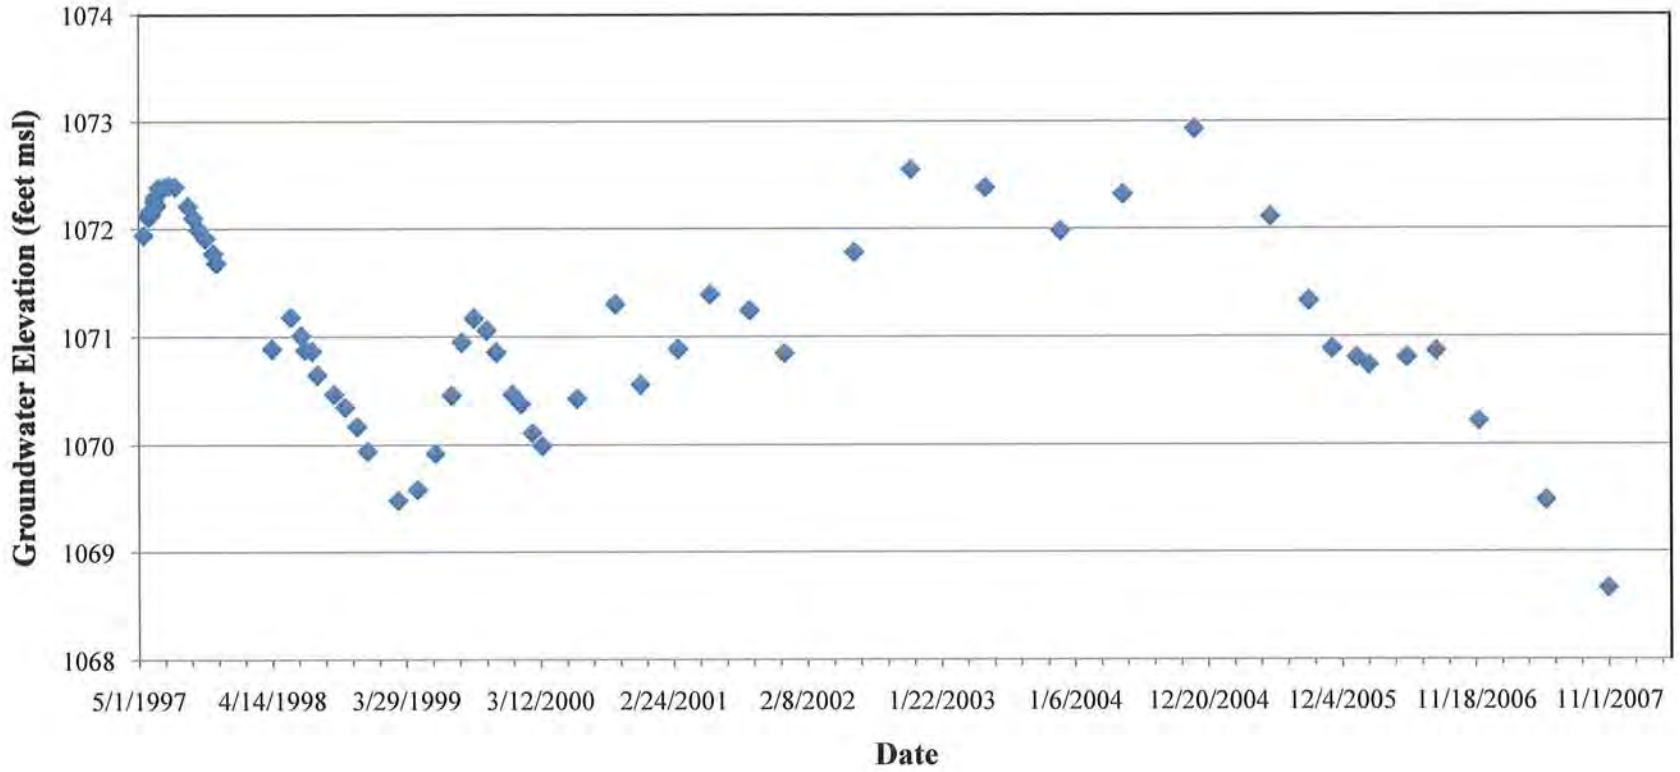
Groundwater Elevations in Well GM-2B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 271-281 Feet Below Ground Surface



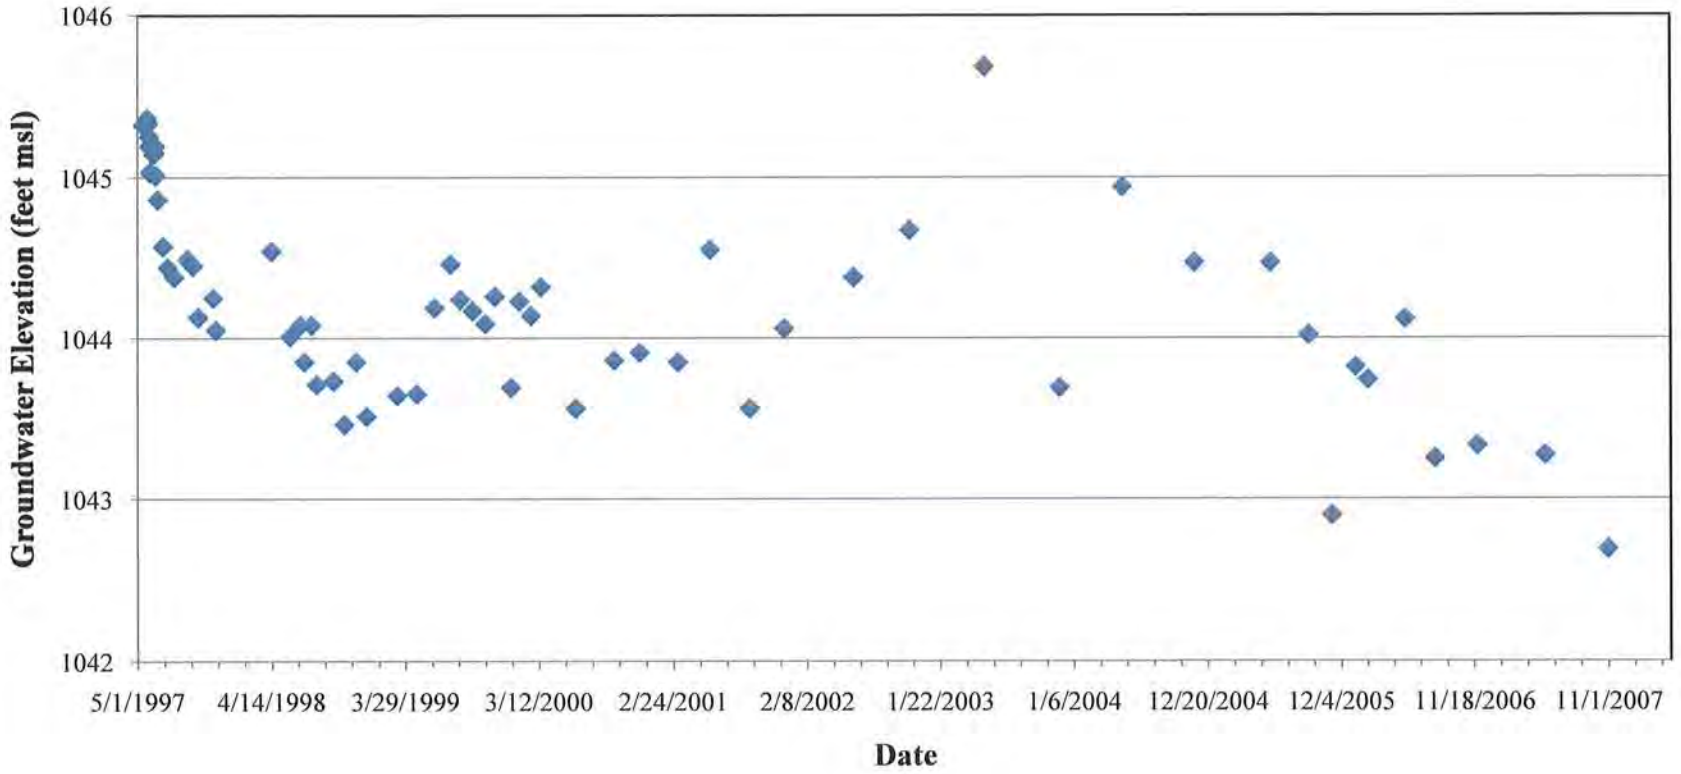
Groundwater Elevations in Well GM-2C
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 64-74 Feet Below Ground Surface



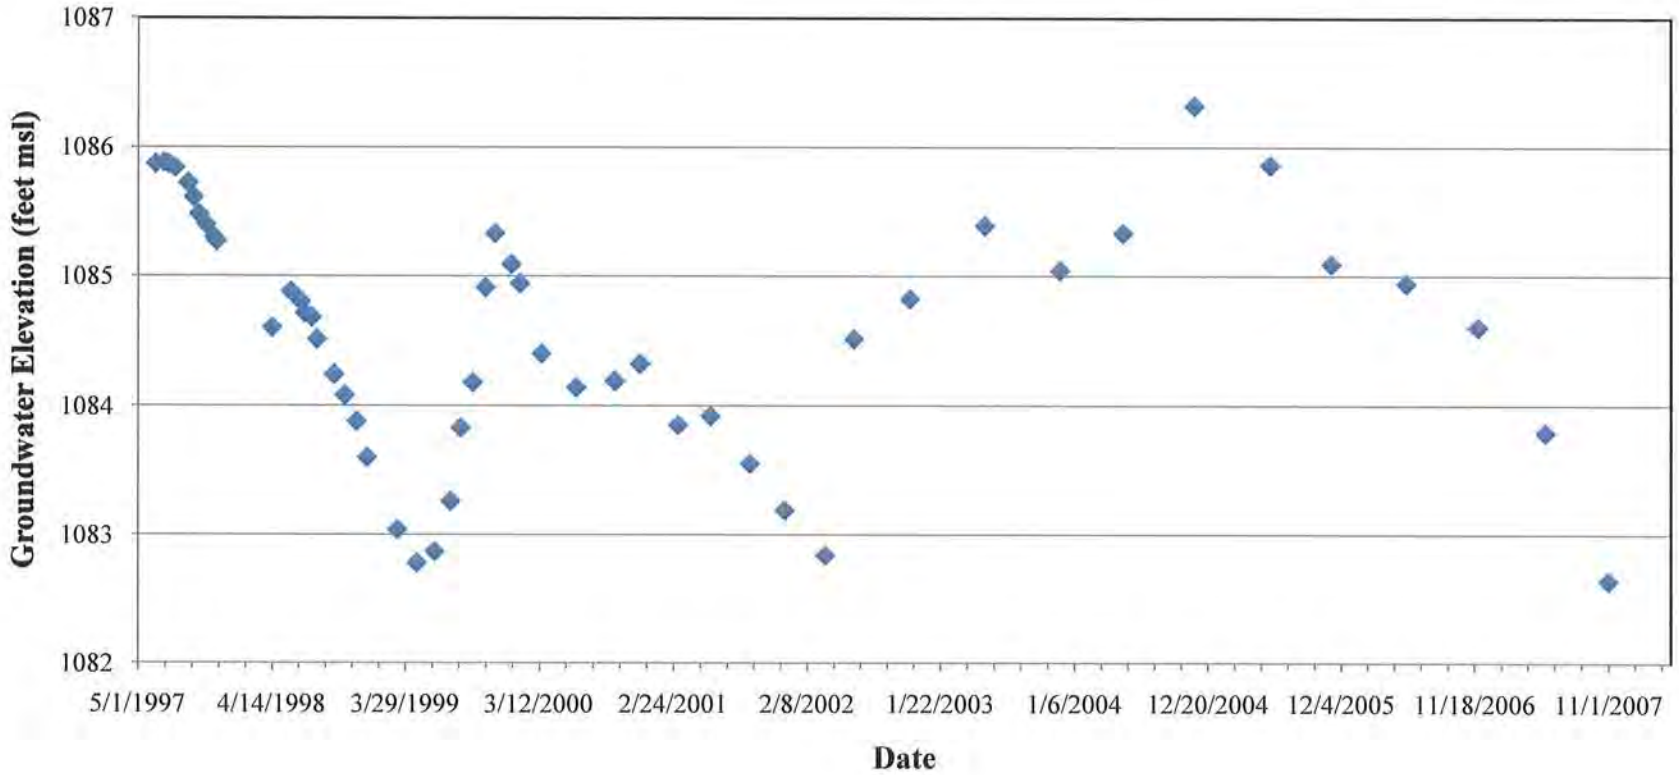
Groundwater Elevations in Well GM-3A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 74-84 Feet Below Ground Surface



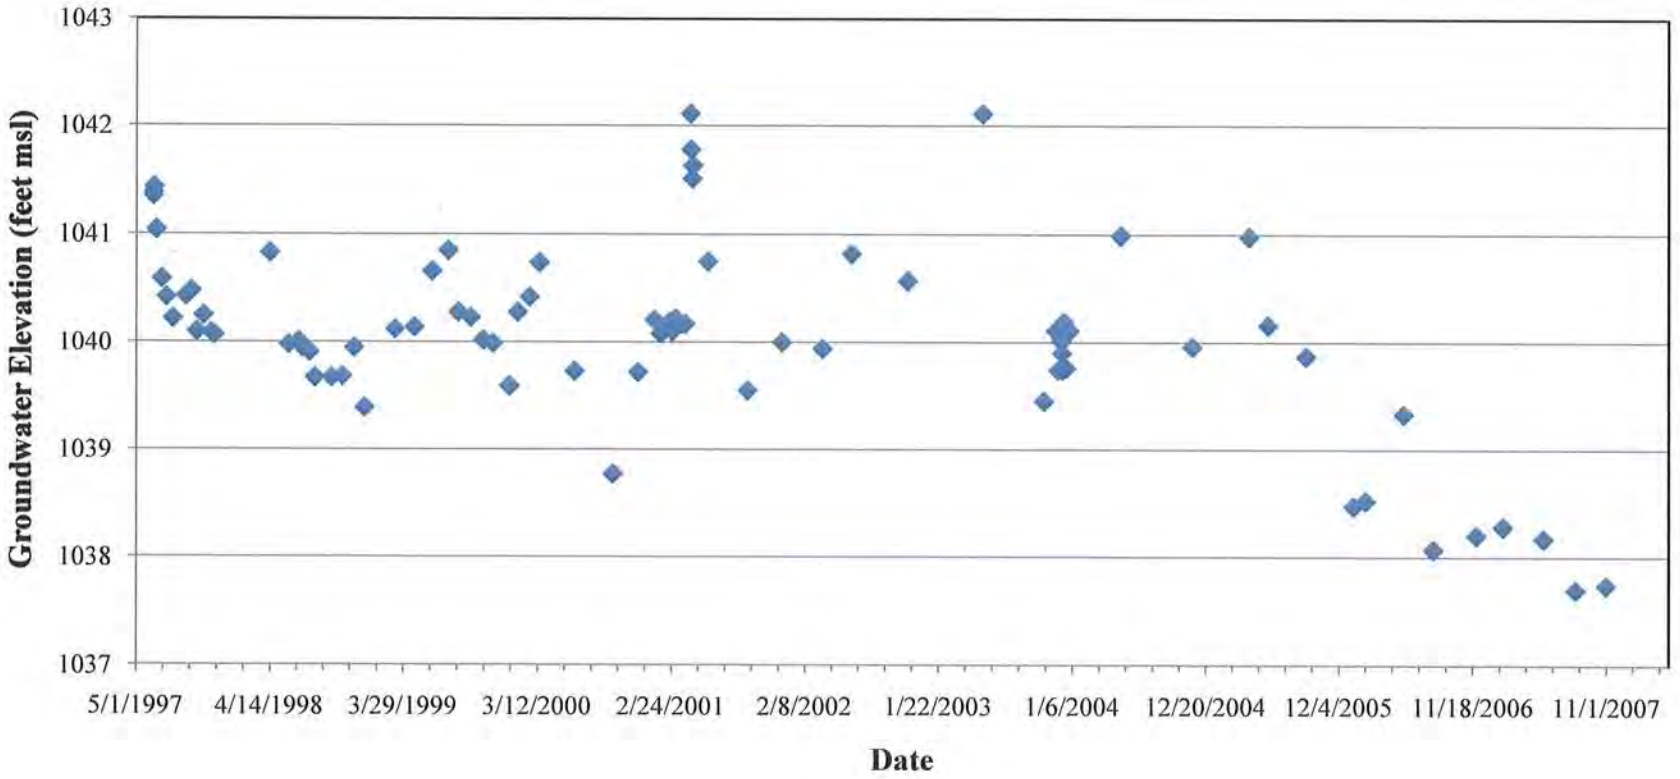
Groundwater Elevations in Well GM-3A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 74-84 Feet Below Ground Surface



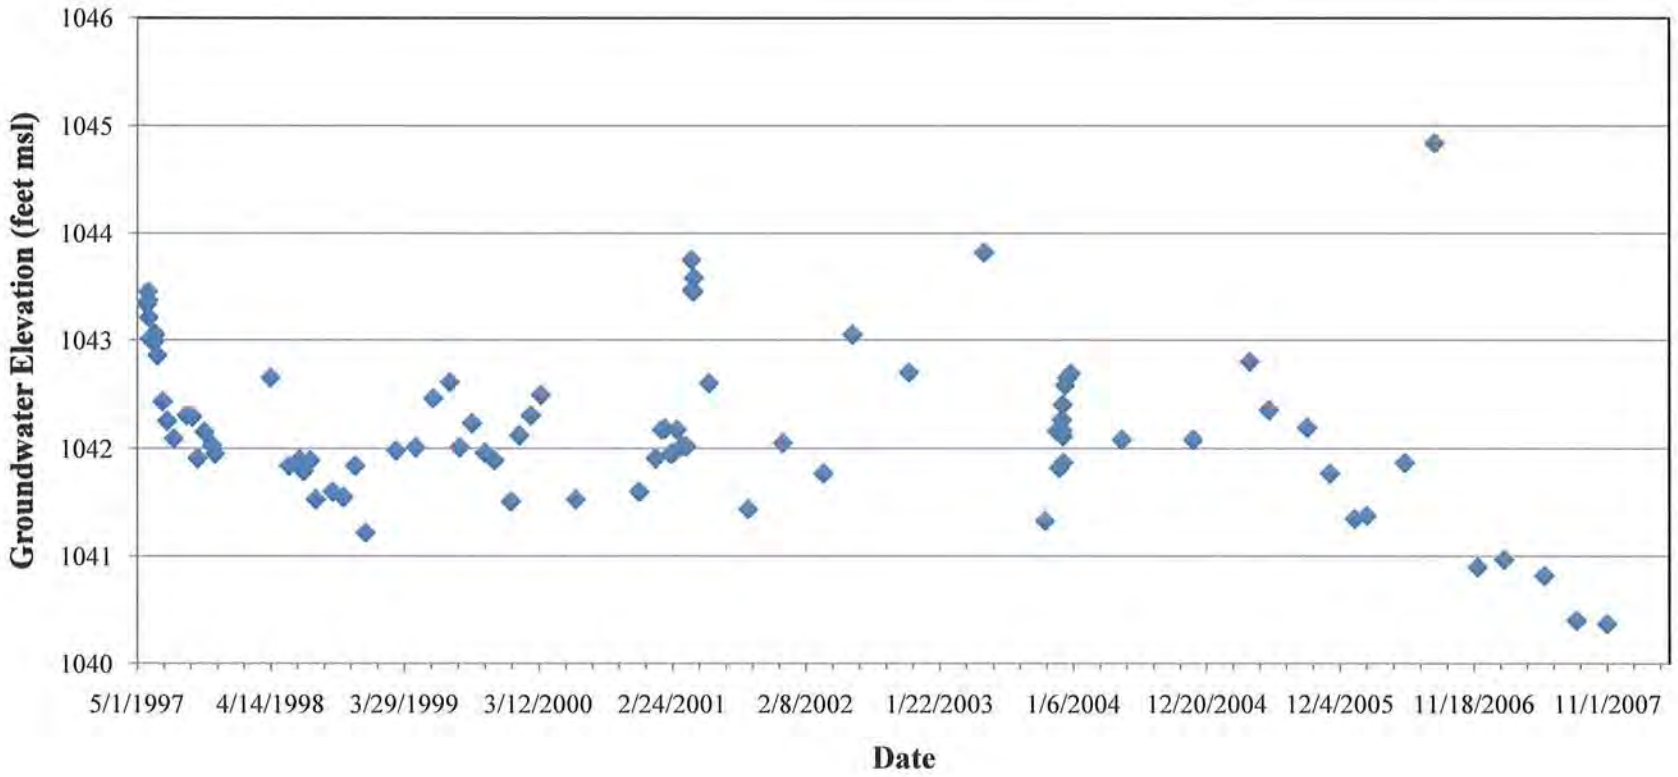
Groundwater Elevations in Well GM-4
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 76-86 Feet Below Ground Surface



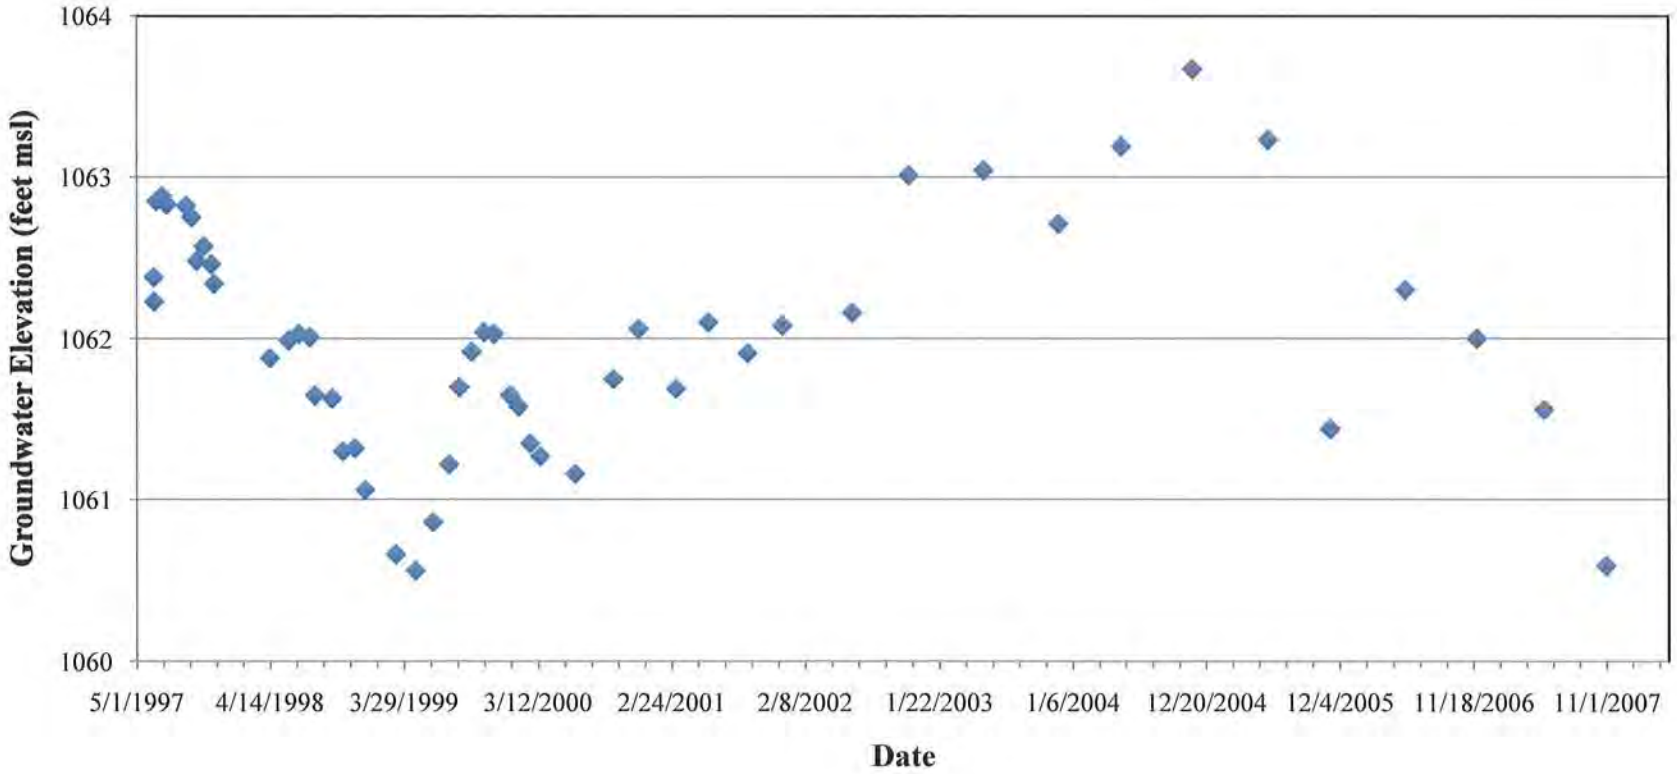
Groundwater Elevations in Well GM-5
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 250-260 Feet Below Ground Surface



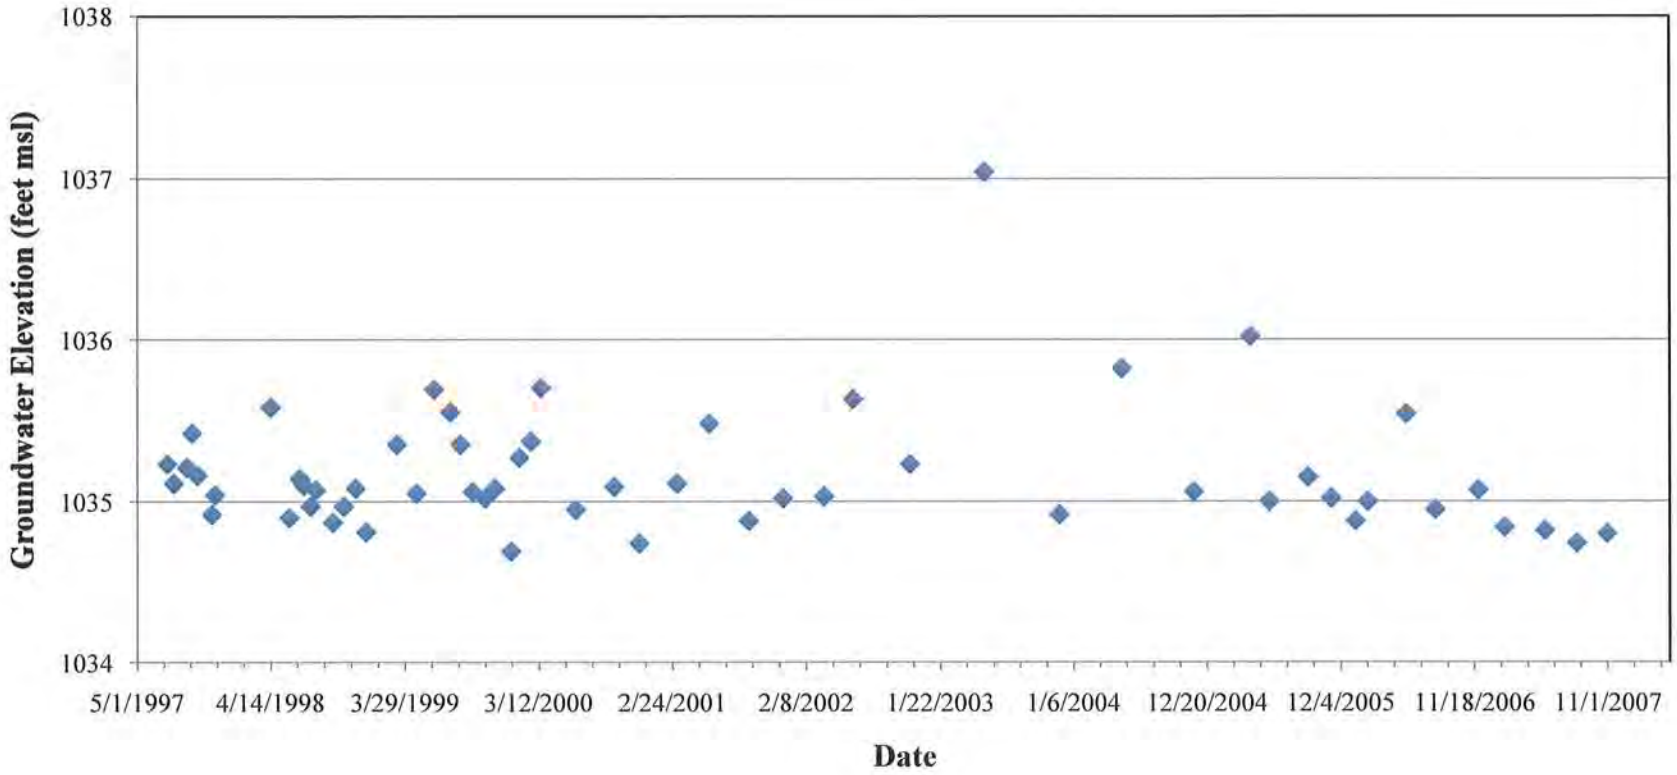
Groundwater Elevations in Well GM-6
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 165-175 Feet Below Ground Surface



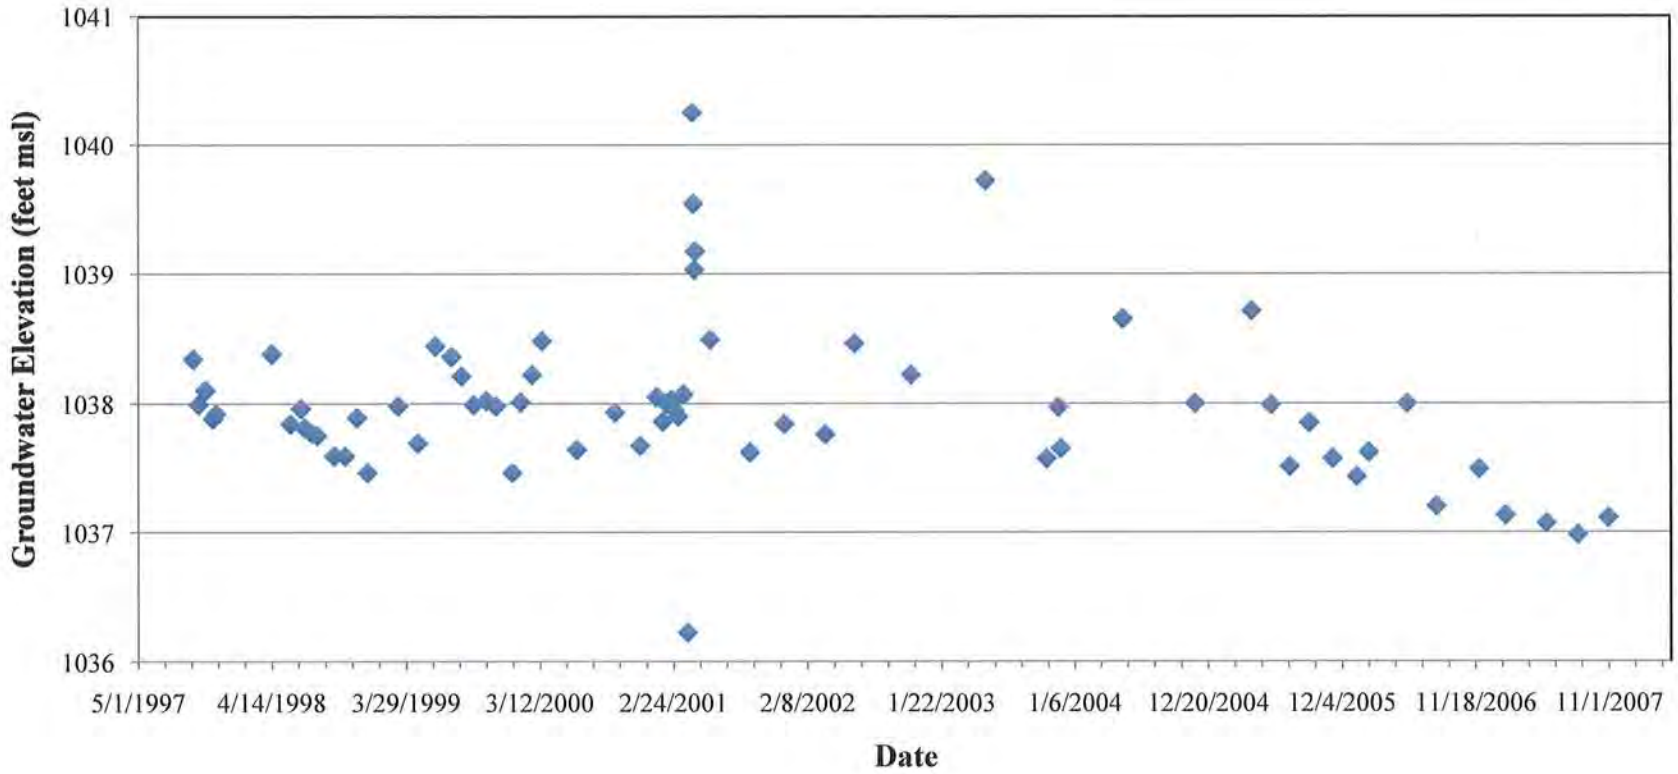
Groundwater Elevations in Well GM-7
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 145-155 Feet Below Ground Surface



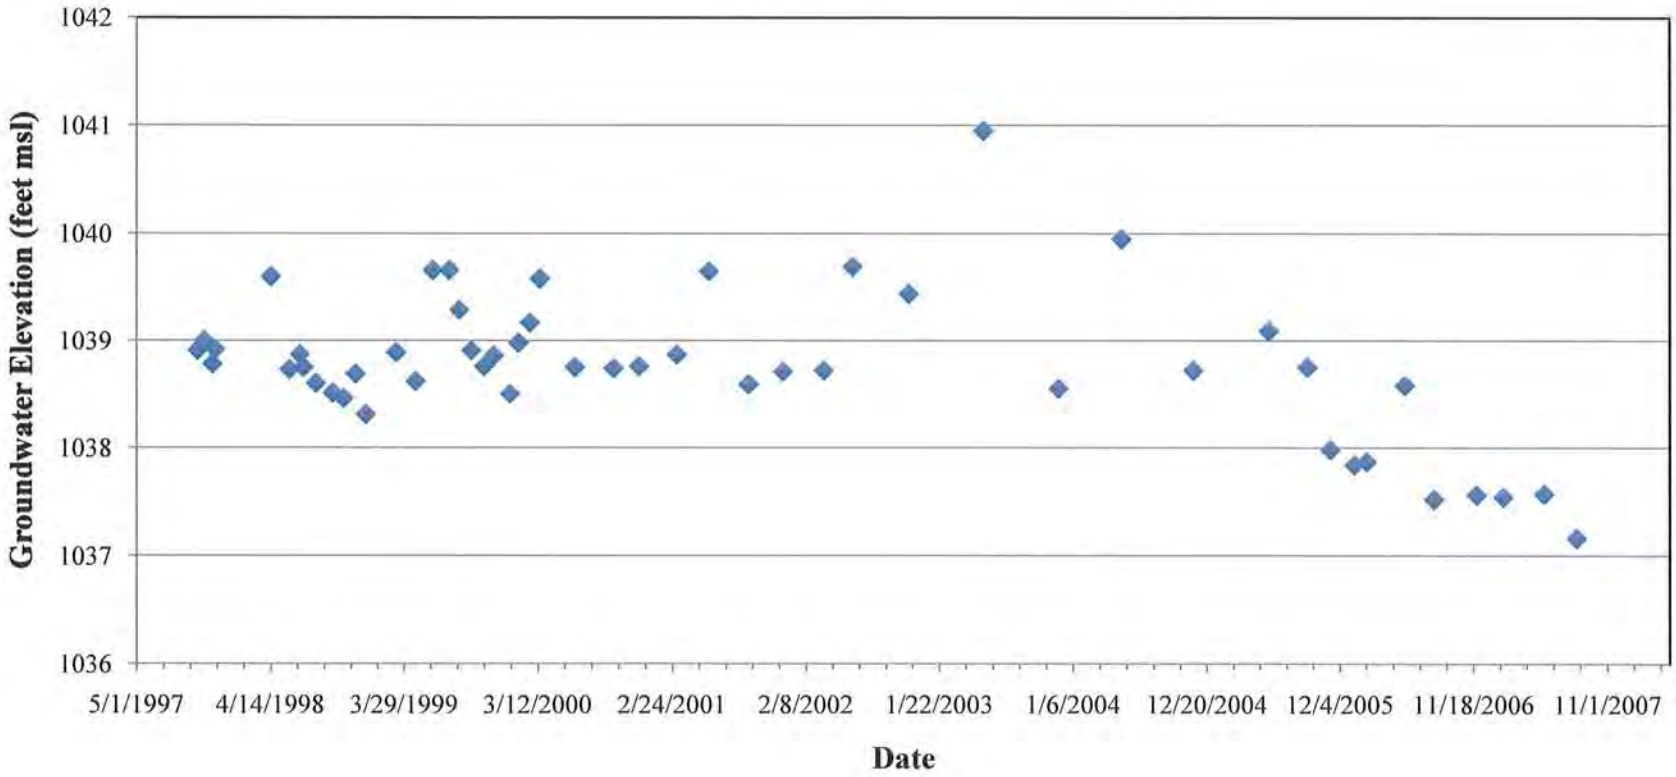
Groundwater Elevations in Well GM-8
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 79-89 Feet Below Ground Surface



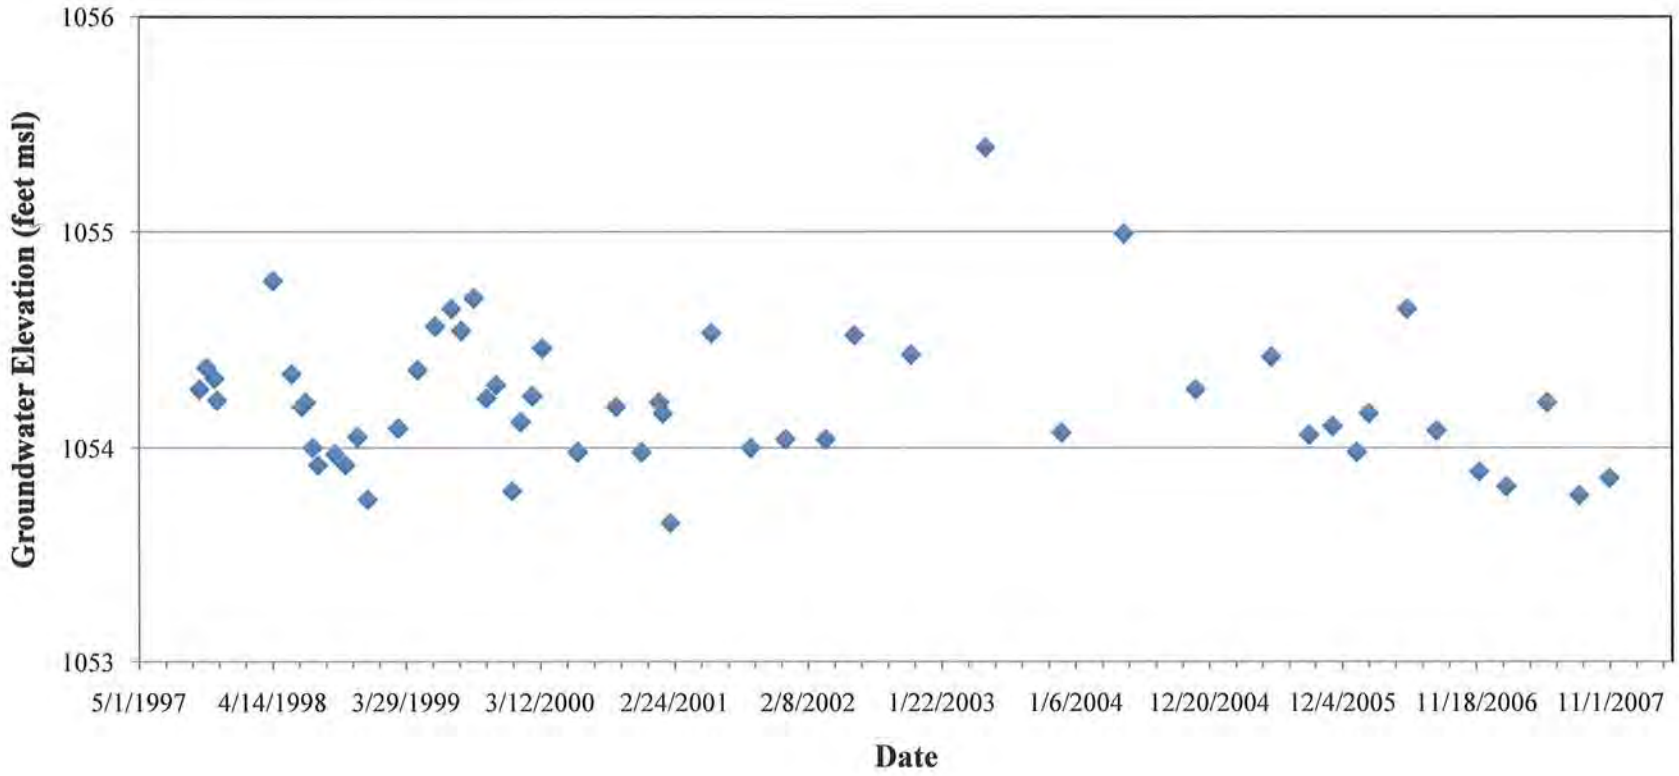
Groundwater Elevations in Well GM-9
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 164-174 Feet Below Ground Surface



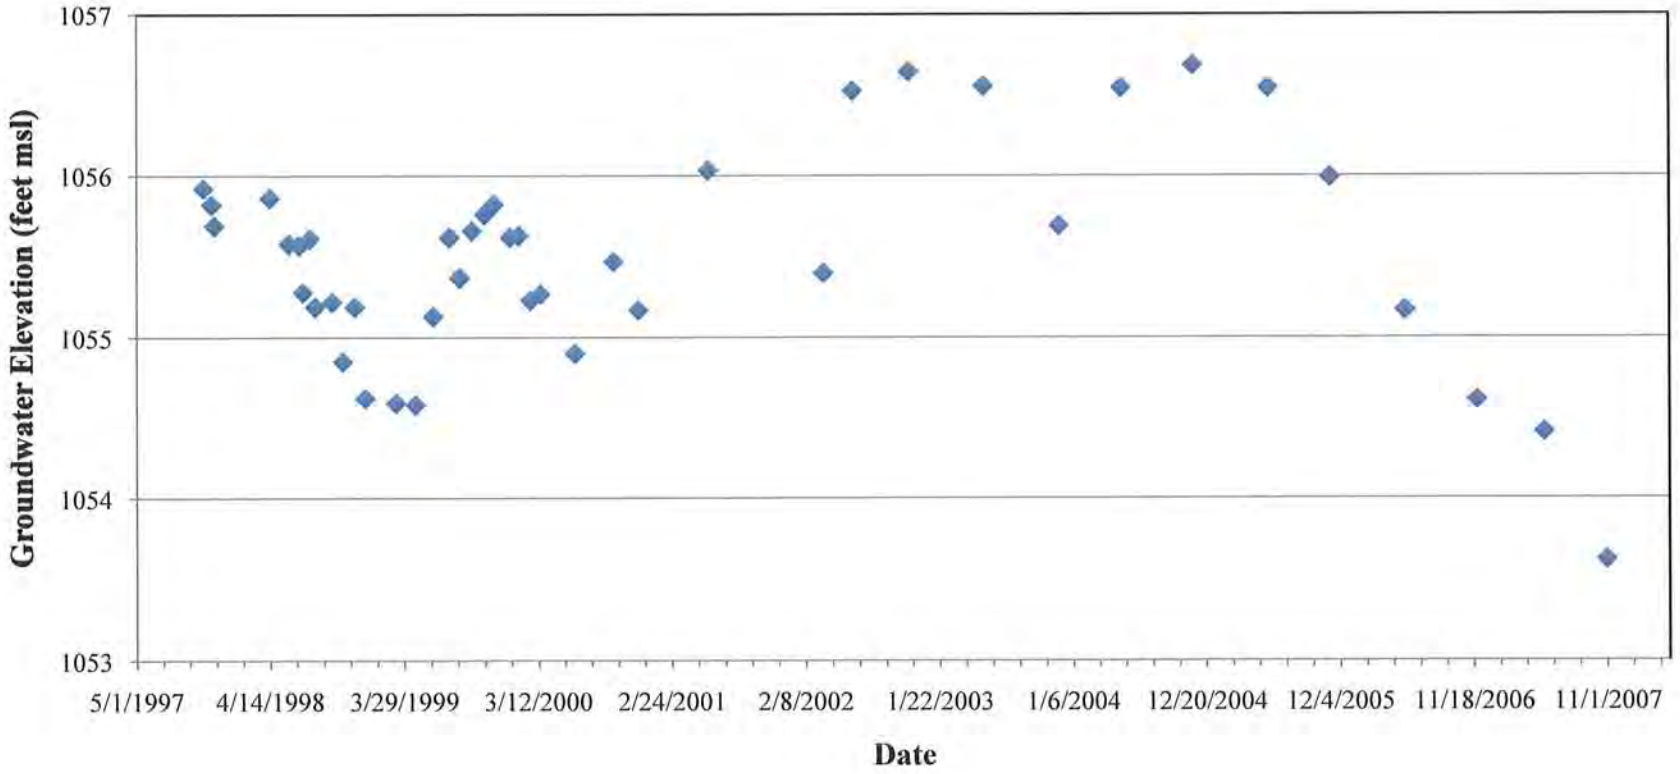
Groundwater Elevations in Well GM-10
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 170-180 Feet Below Ground Surface



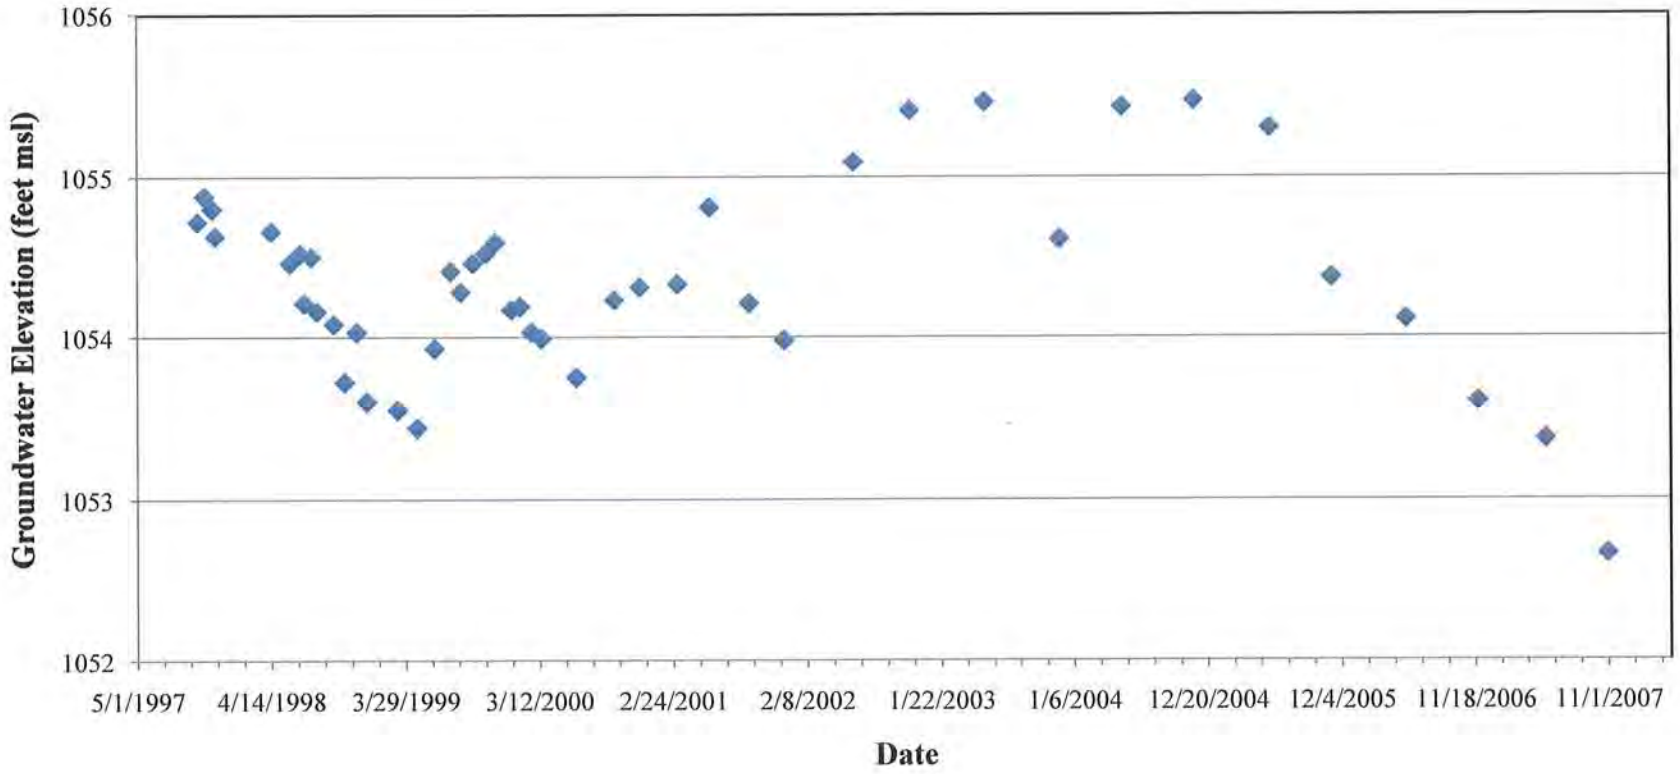
Groundwater Elevations in Well GM-11
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 174.7-184.7 Feet Below Ground Surface



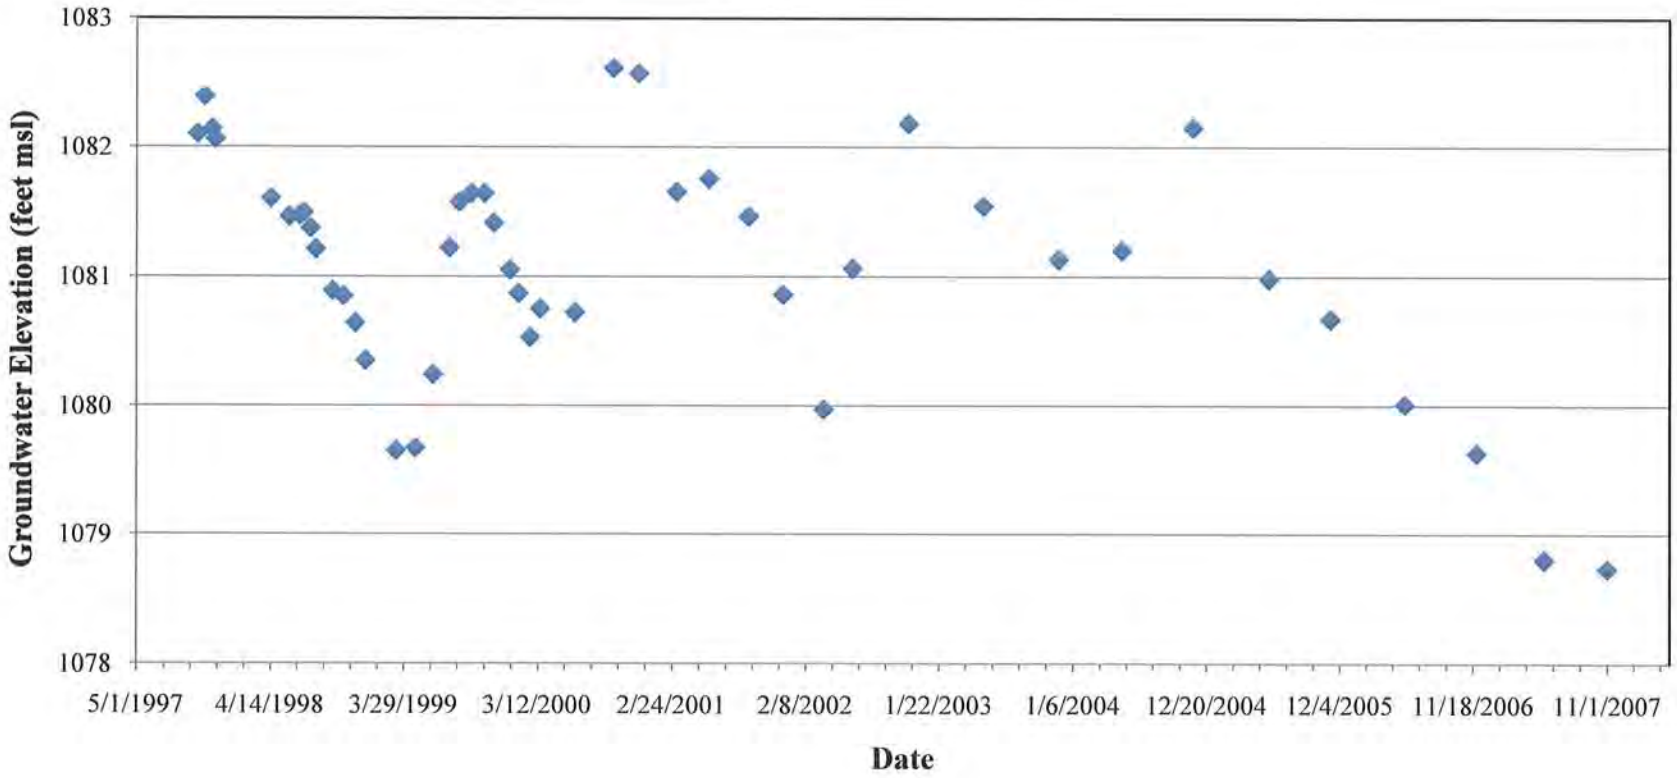
Groundwater Elevations in Well GM-12
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 290-300 Feet Below Ground Surface



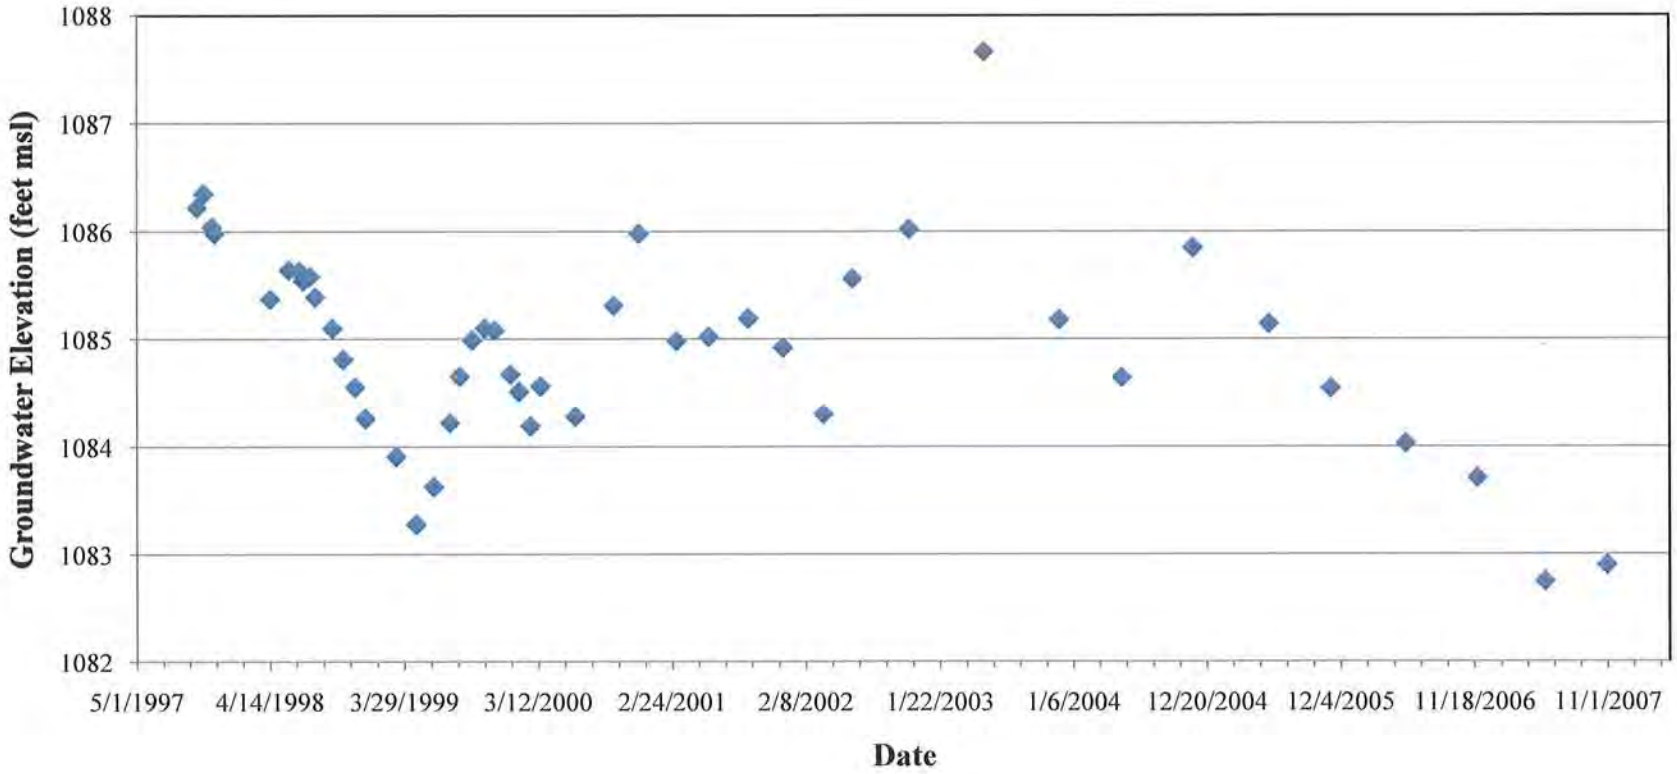
Groundwater Elevations in Well GM-13
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 325-335 Feet Below Ground Surface



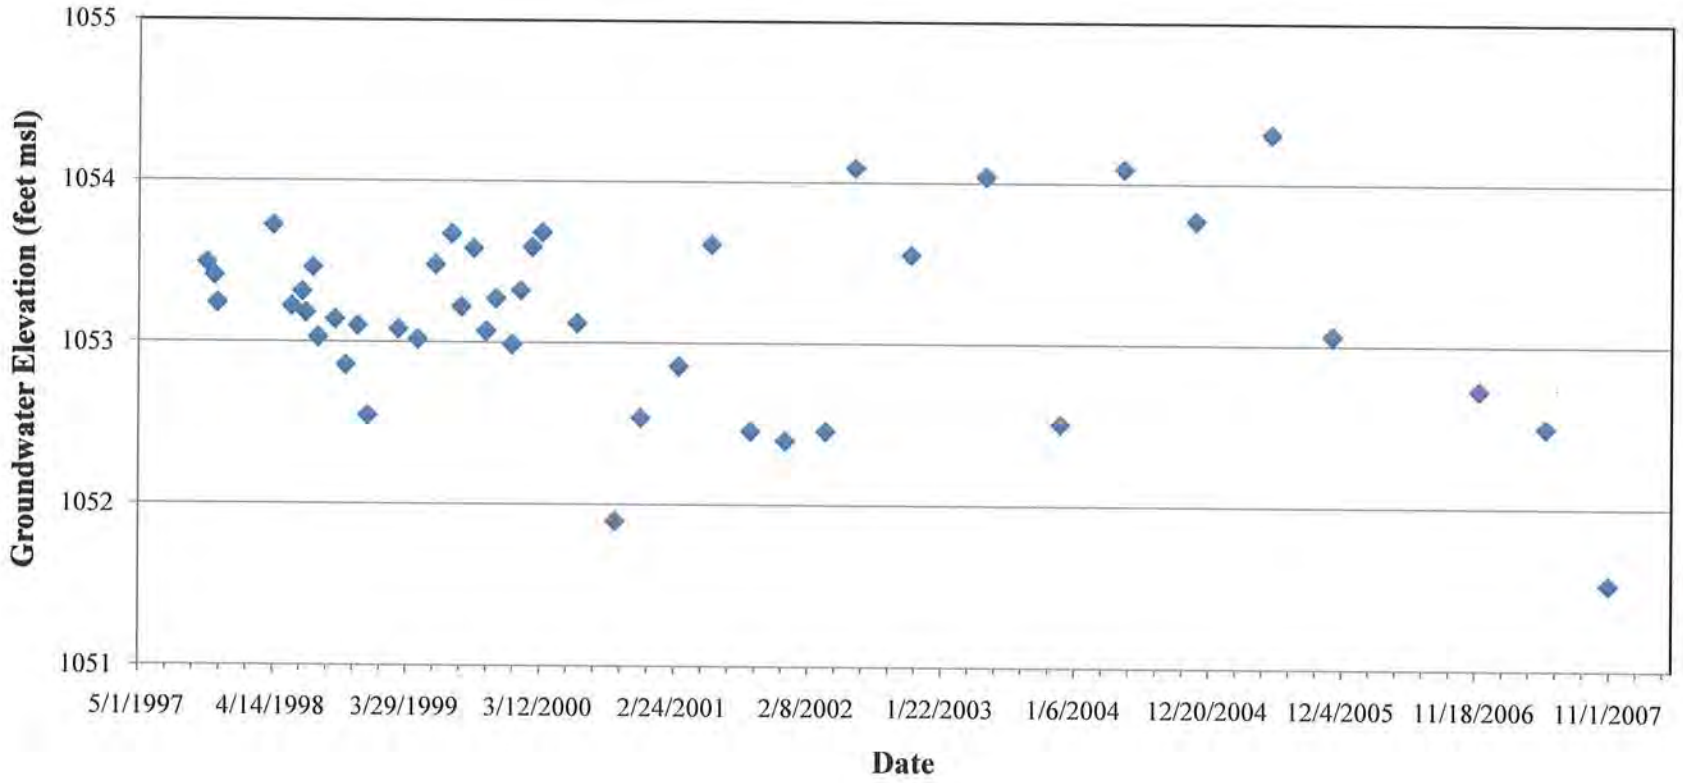
Groundwater Elevations in Well GM-14
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 135-145 Feet Below Ground Surface



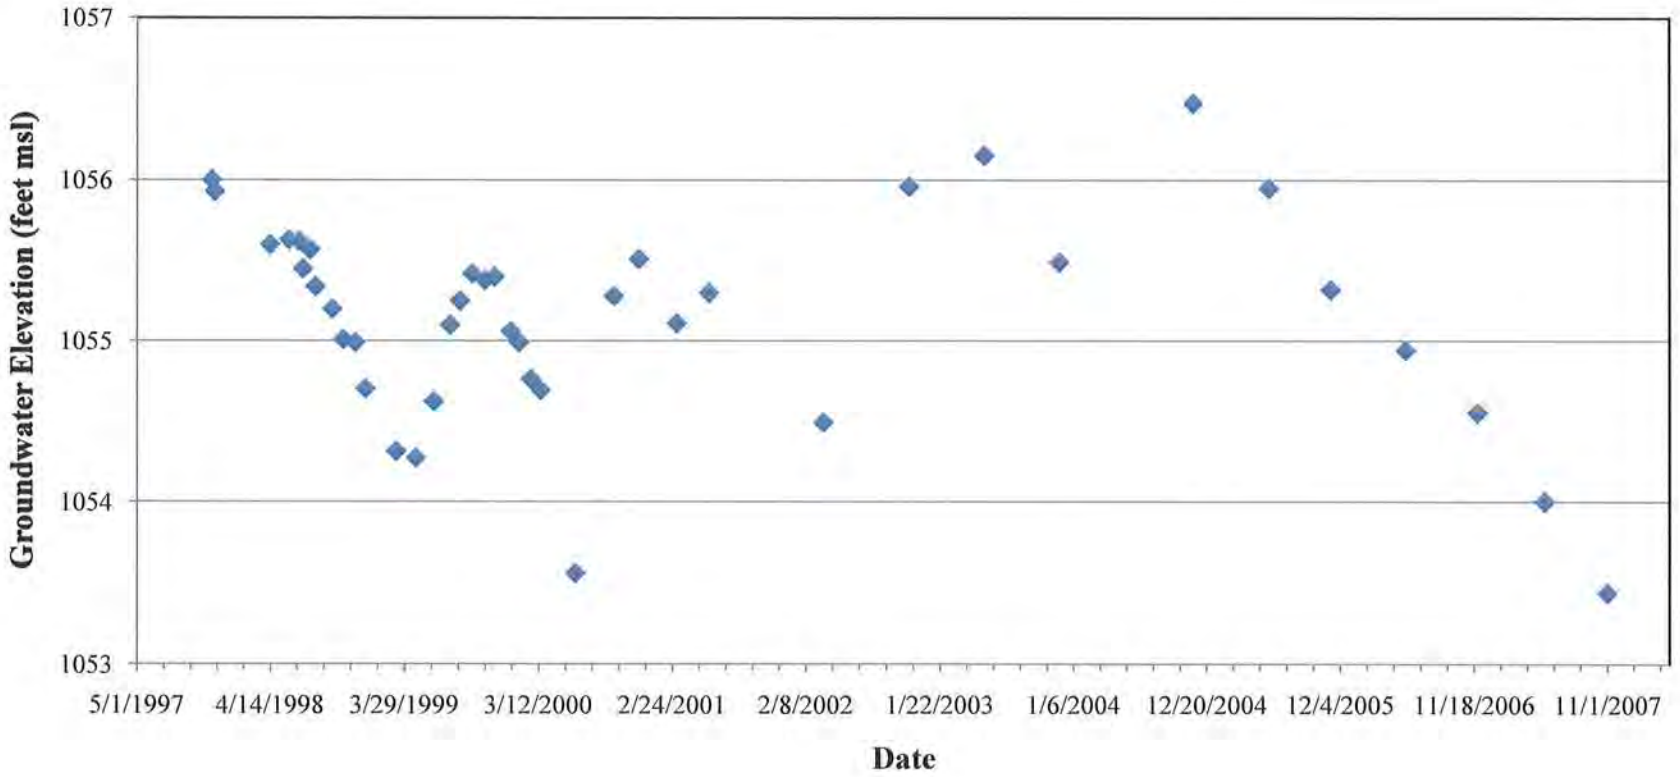
Groundwater Elevations in Well GM-15
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 165-175 Feet Below Ground Surface



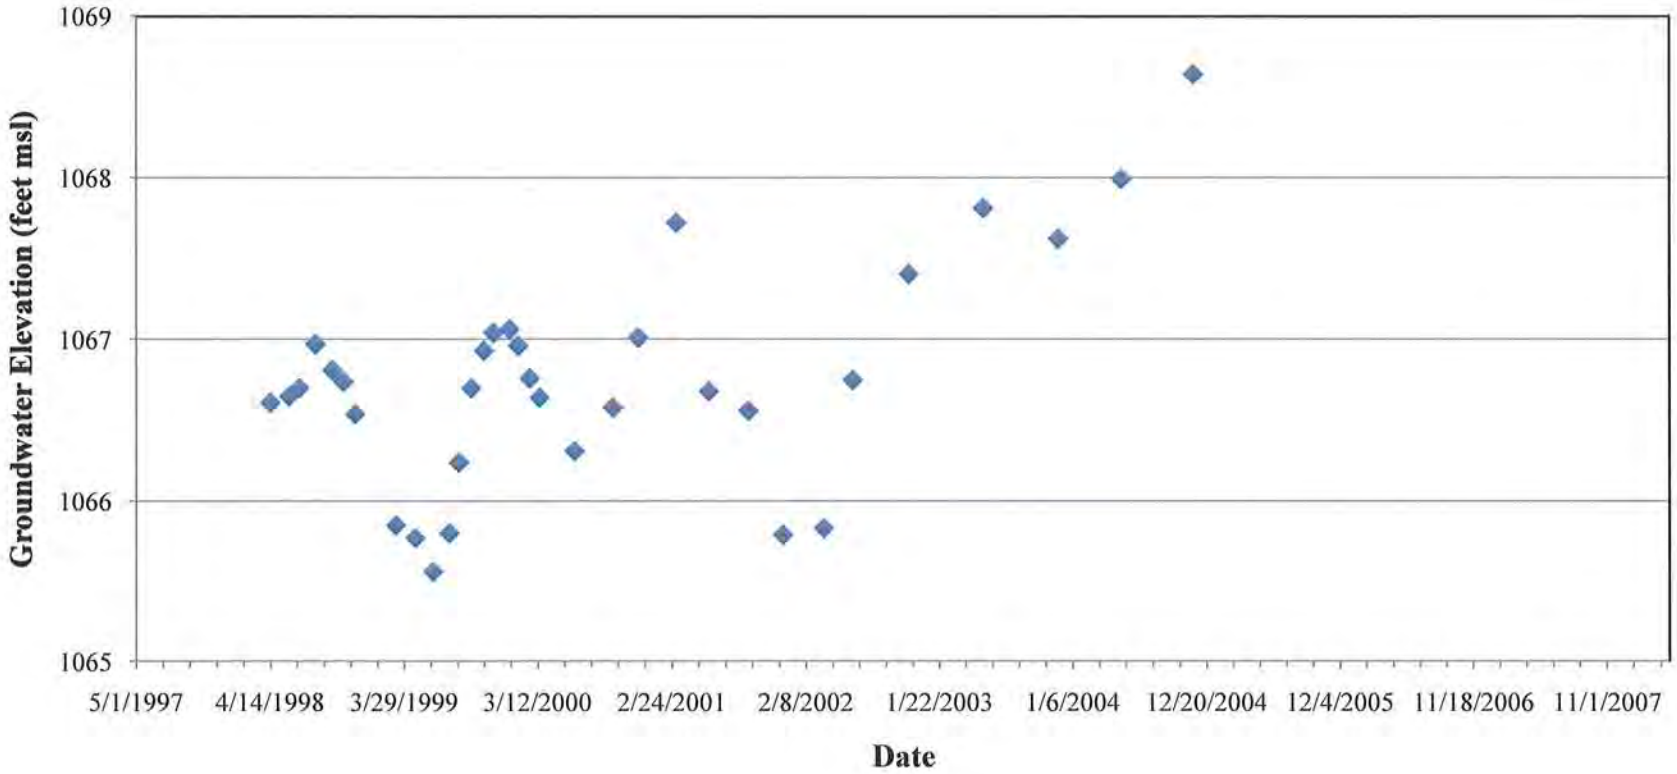
Groundwater Elevations in Well GM-16
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 108-118 Feet Below Ground Surface



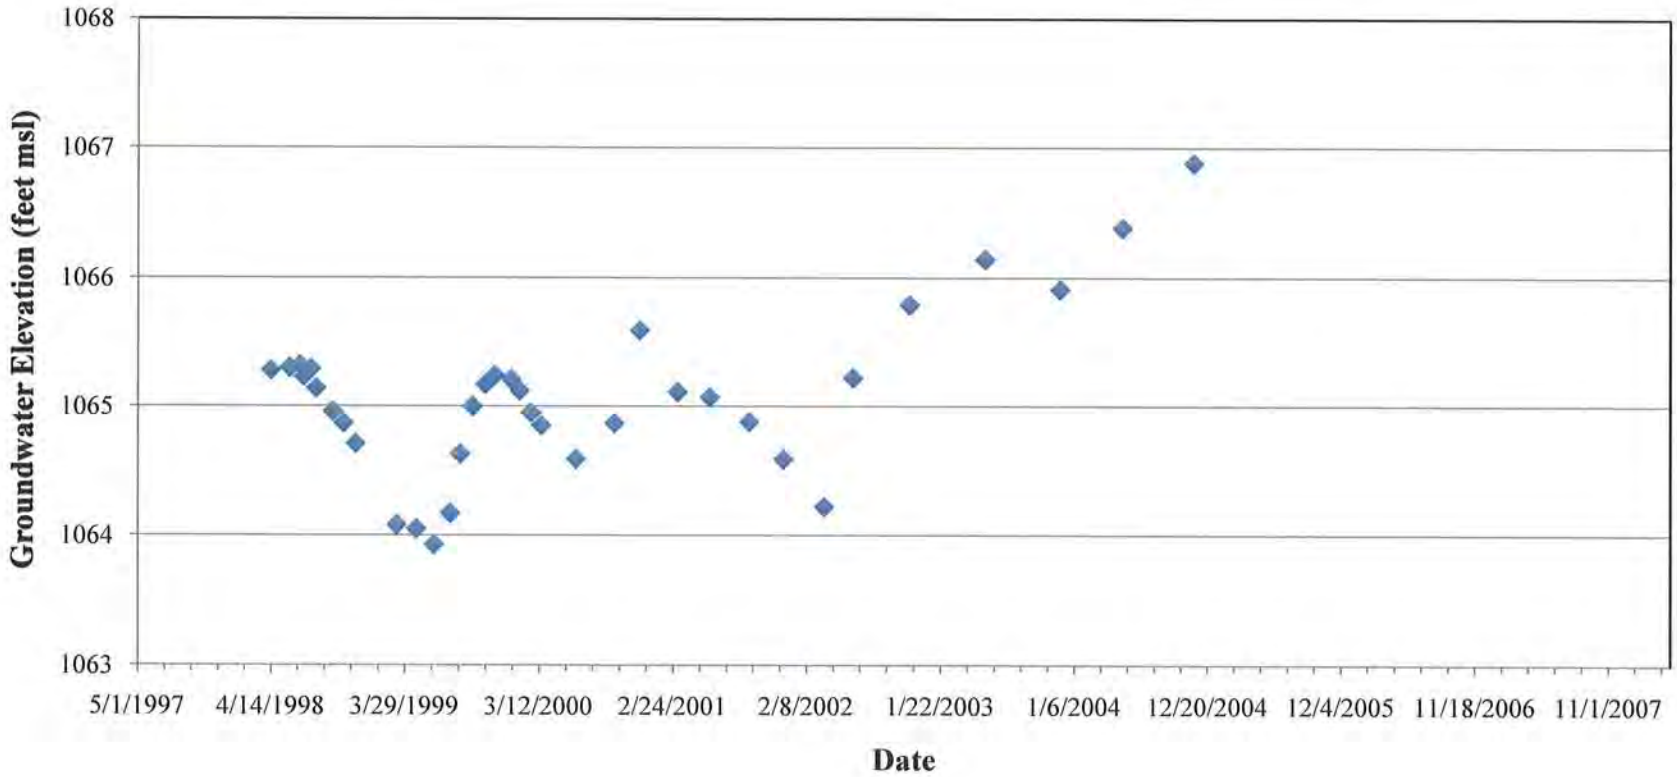
Groundwater Elevations in Well GM-17
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 224.3-234.3 Feet Below Ground Surface



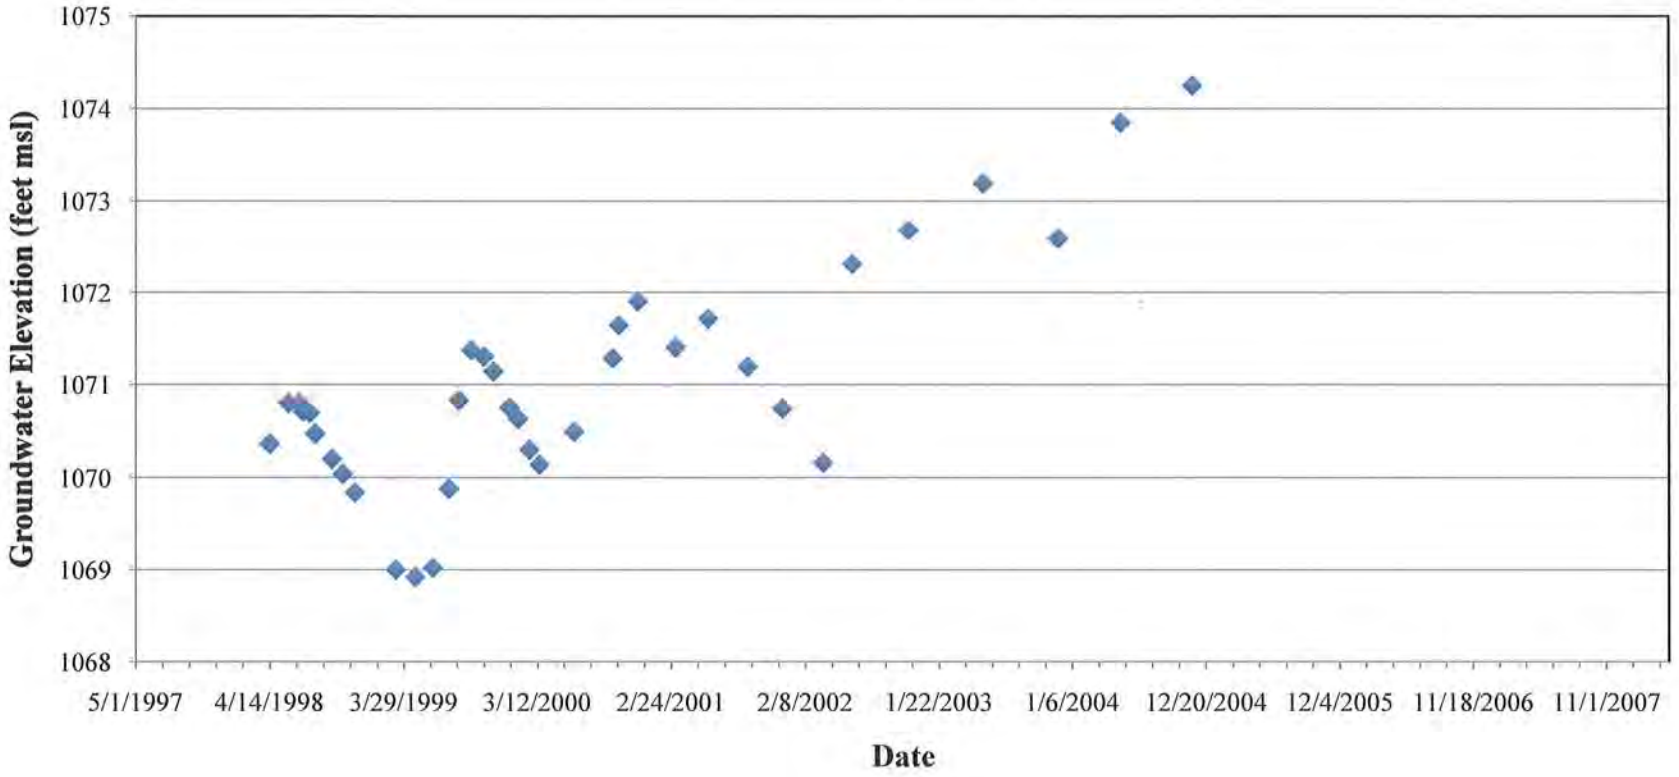
Groundwater Elevations in Well GM-18
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 50-60 Feet Below Ground Surface



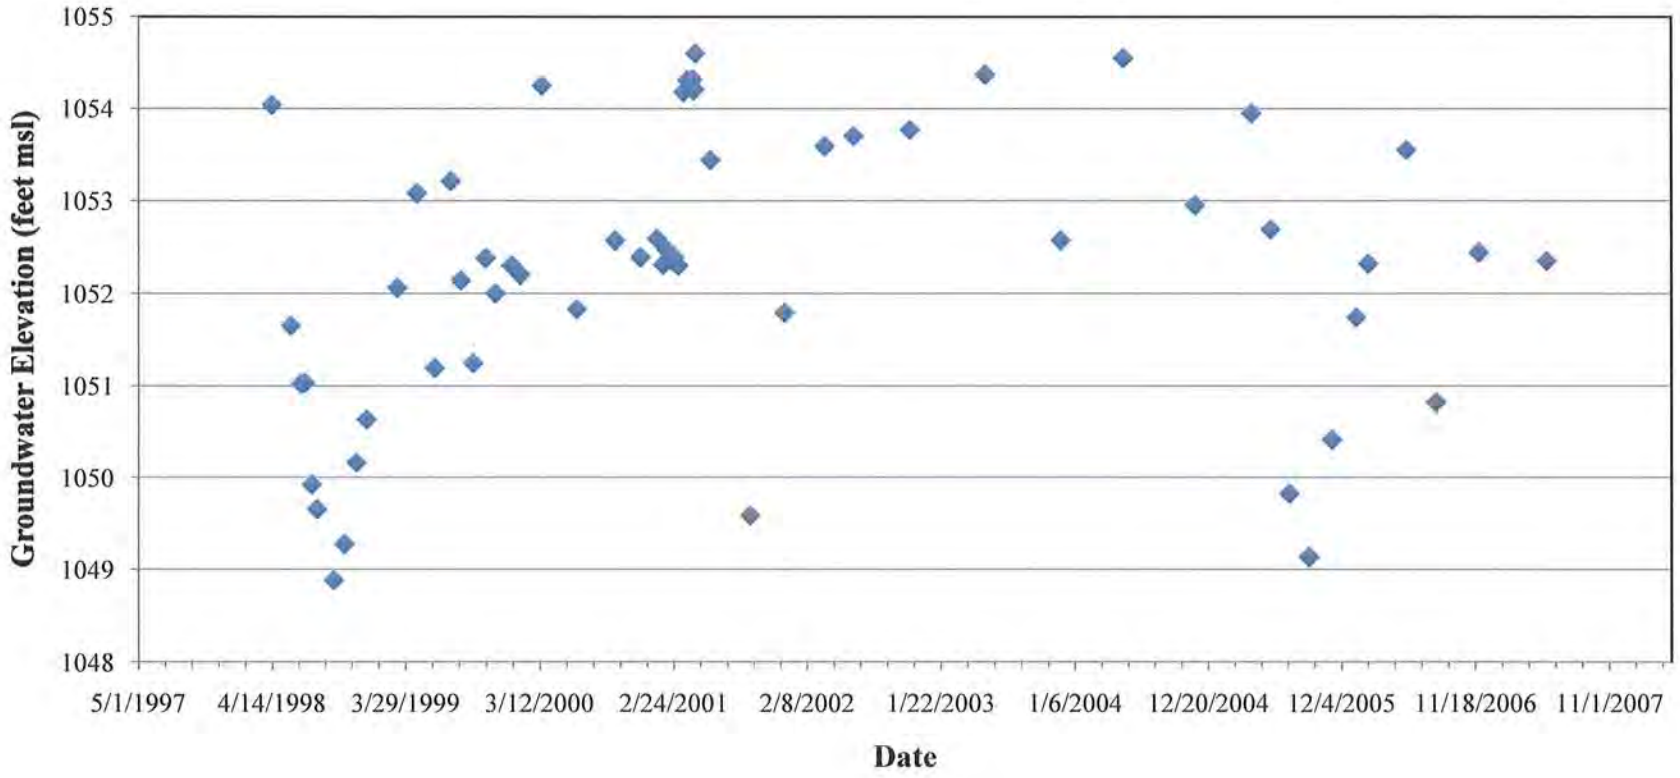
Groundwater Elevations in Well GM-19
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 46-56 Feet Below Ground Surface



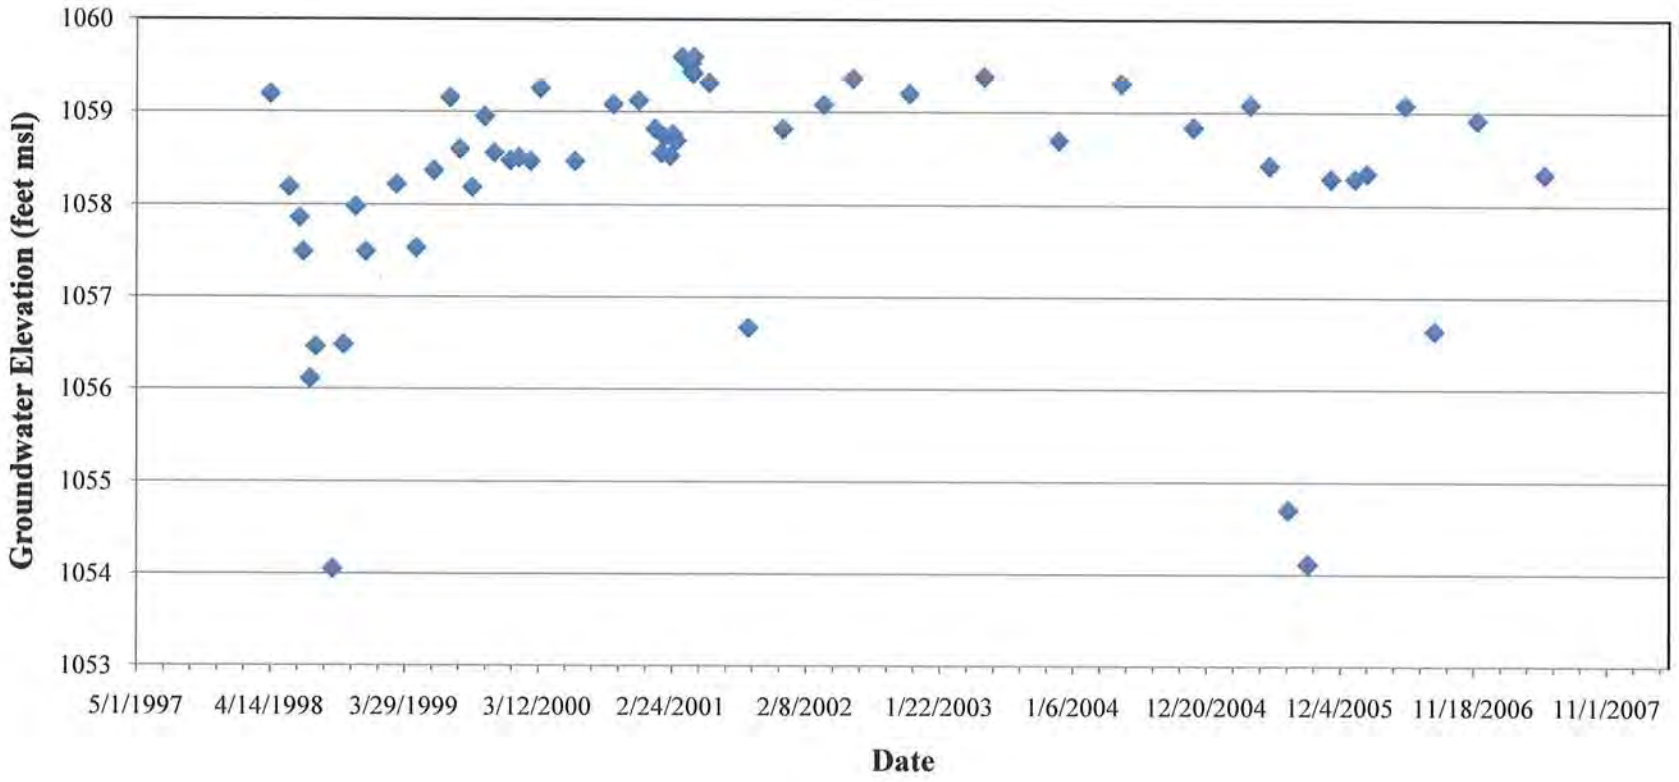
Groundwater Elevations in Well GM-20
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 42-52 Feet Below Ground Surface



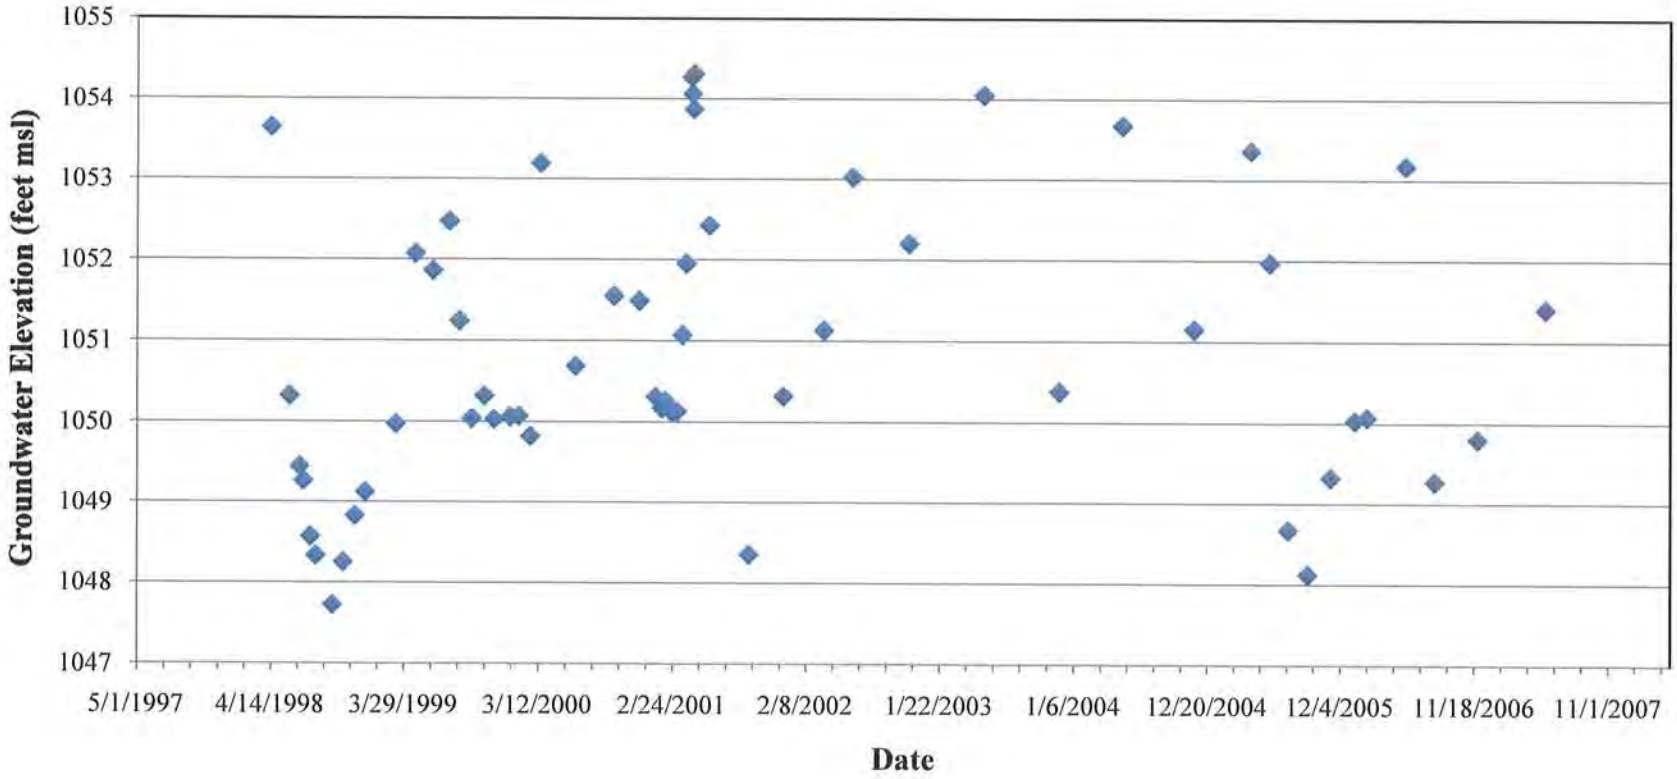
Groundwater Elevations in Well GM-21
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 5-15 Feet Below Ground Surface



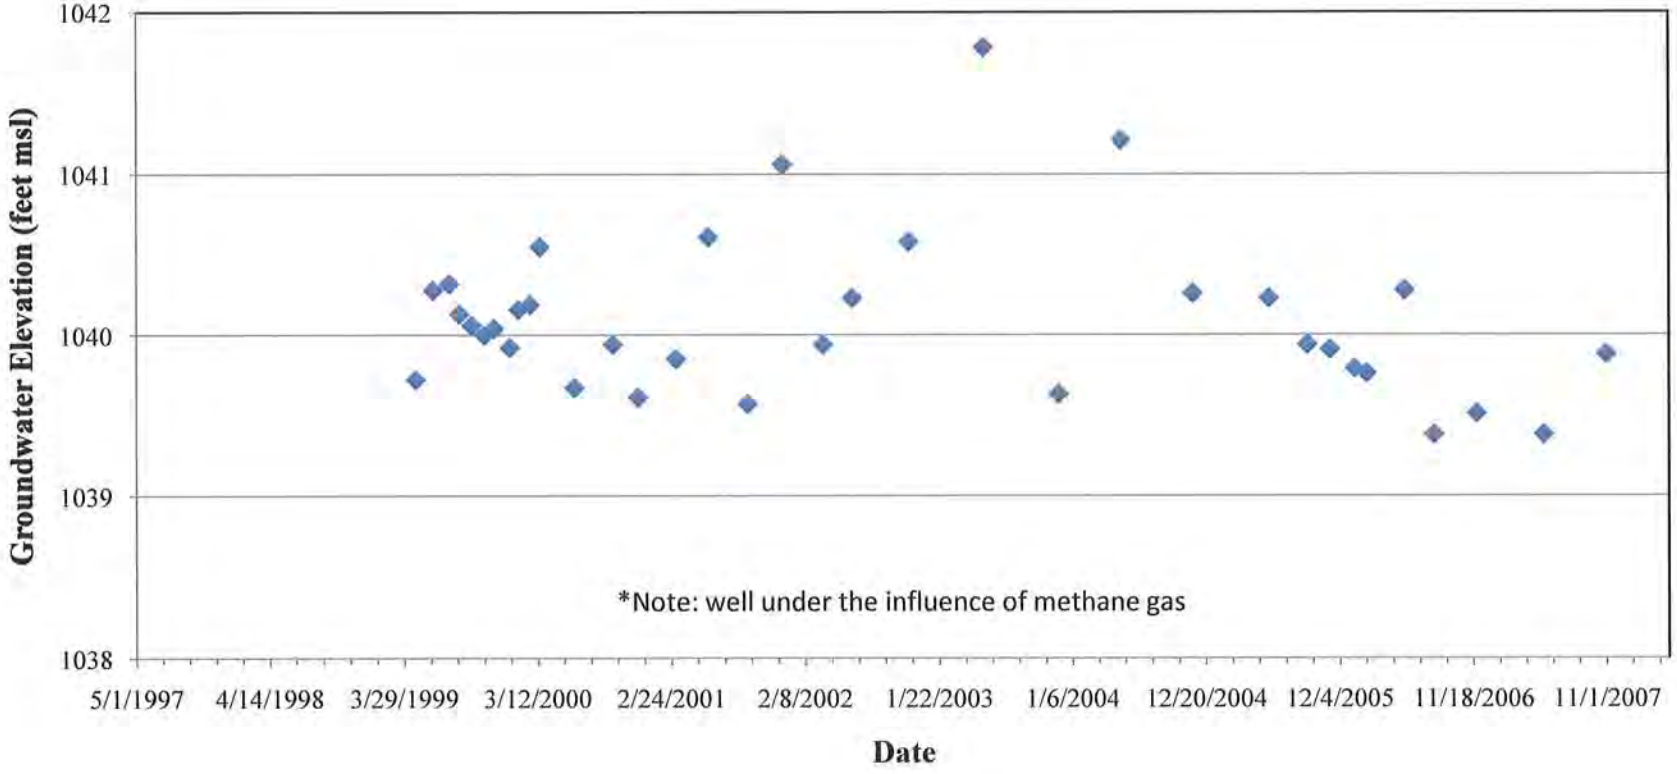
Groundwater Elevations in Well GM-22
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 6-16 Feet Below Ground Surface



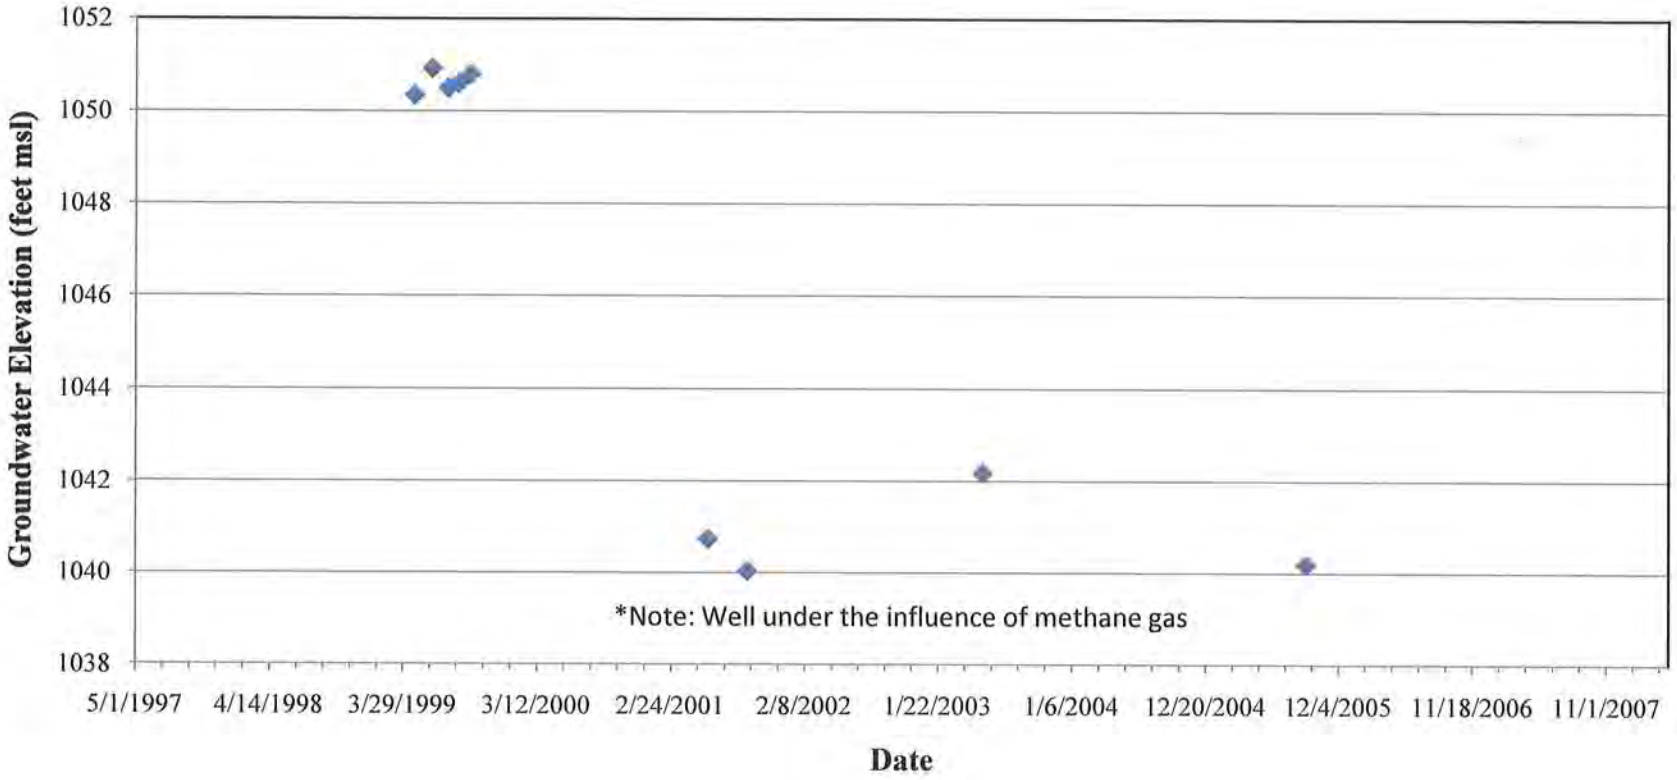
Groundwater Elevations in Well GM-23
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 3.5-13.5 Feet Below Ground Surface



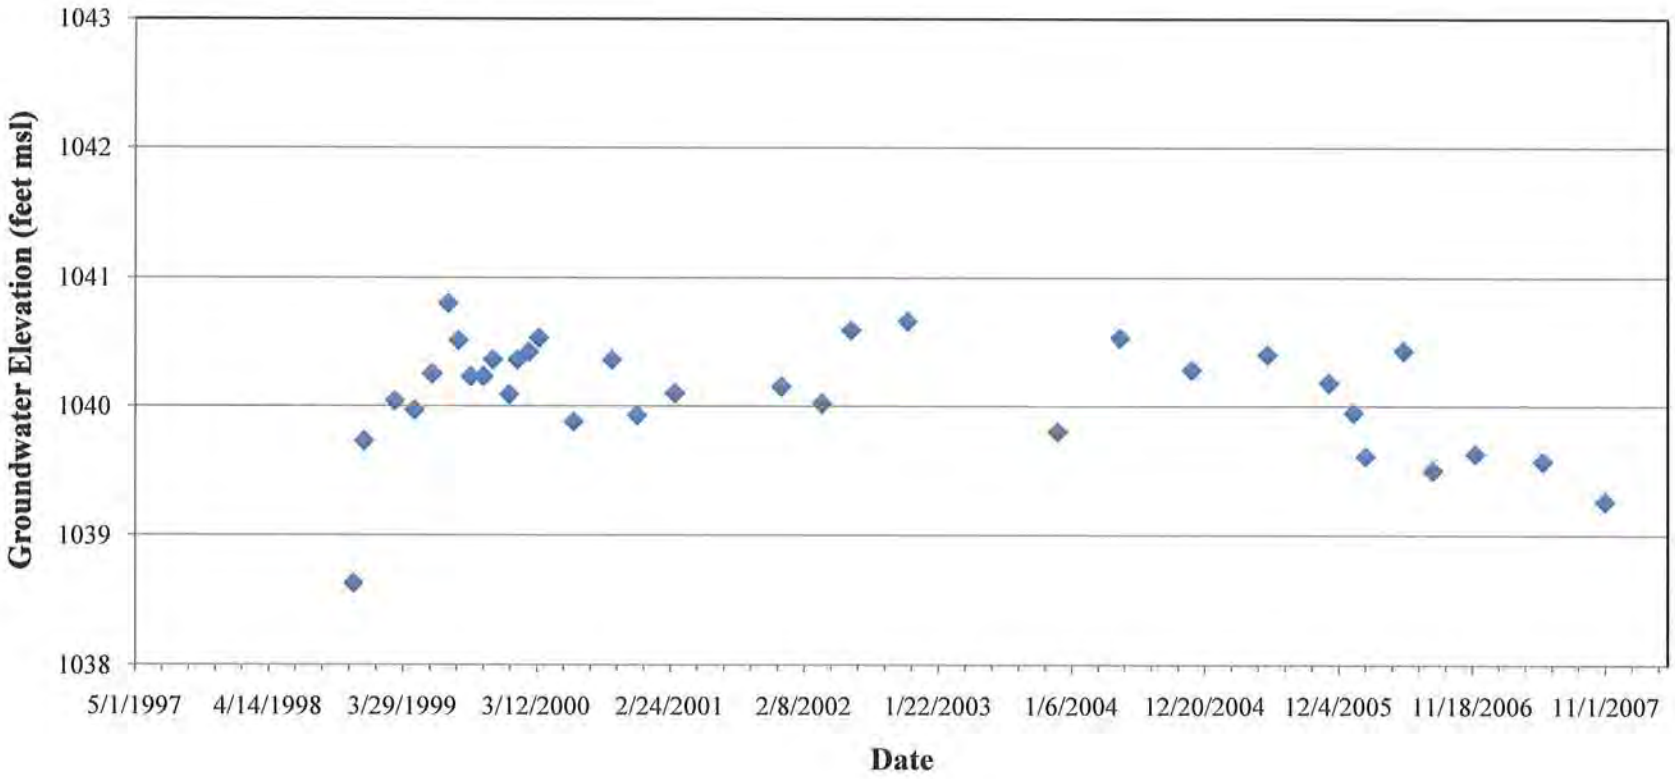
Groundwater Elevations in Well GM-24A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 71-81 Feet Below Ground Surface



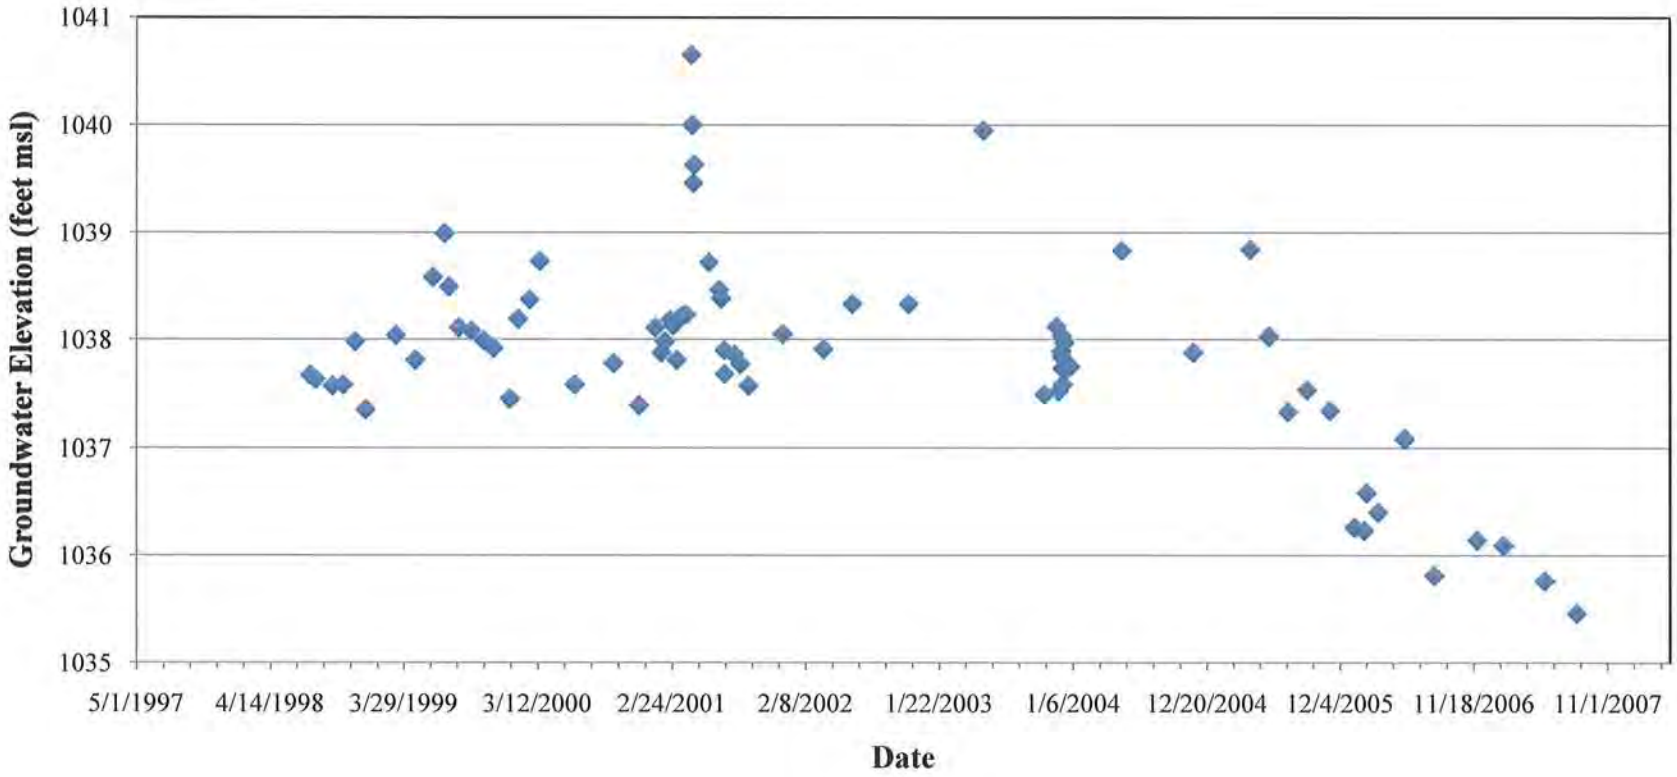
Groundwater Elevations in Well GM-24B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 104-114 Feet Below Ground Surface



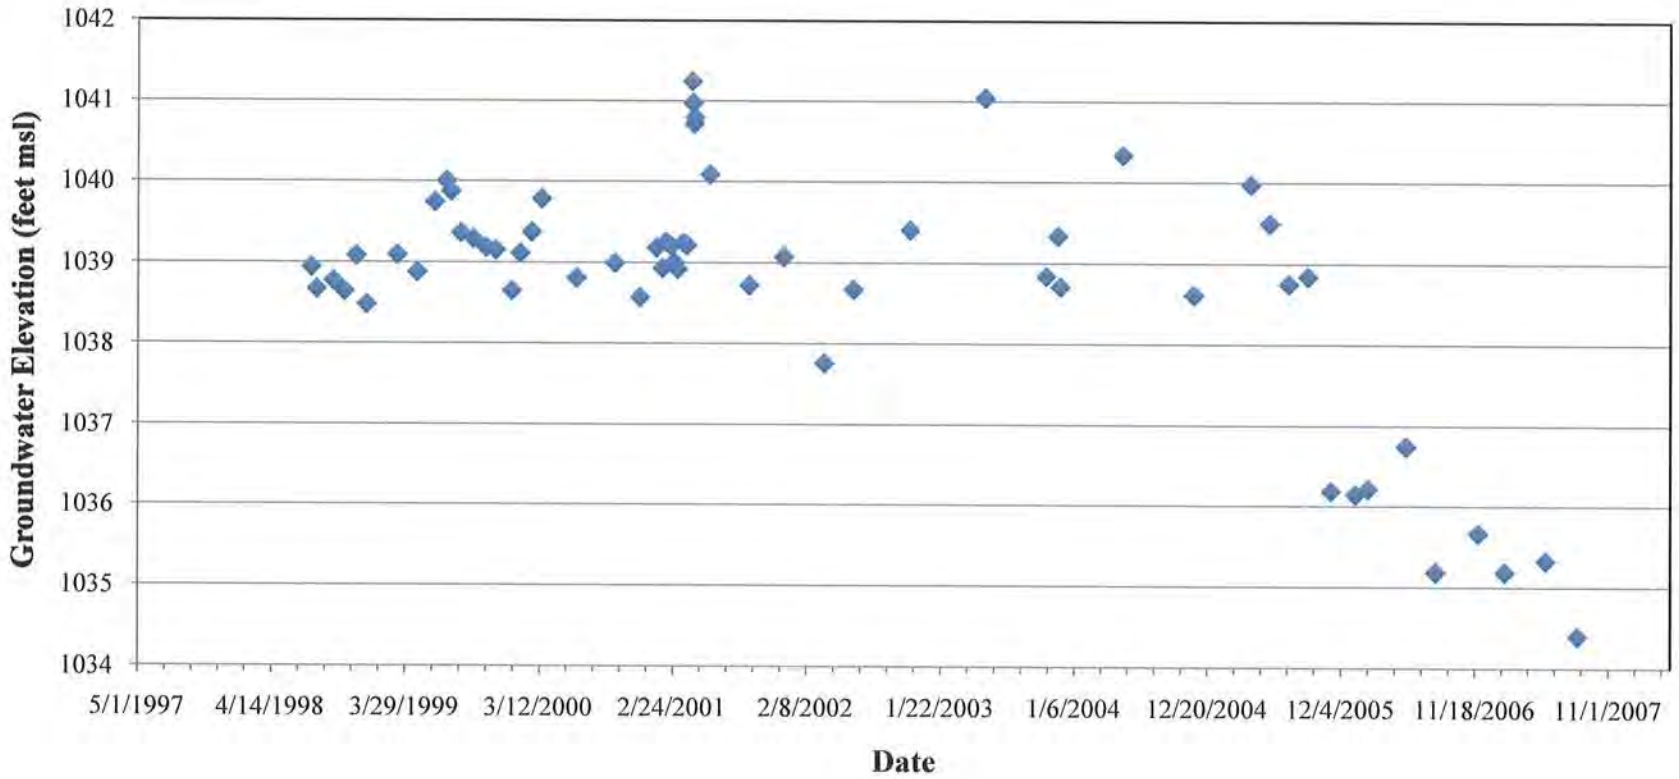
Groundwater Elevations in Well GM-24C
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 193-198 Feet Below Ground Surface



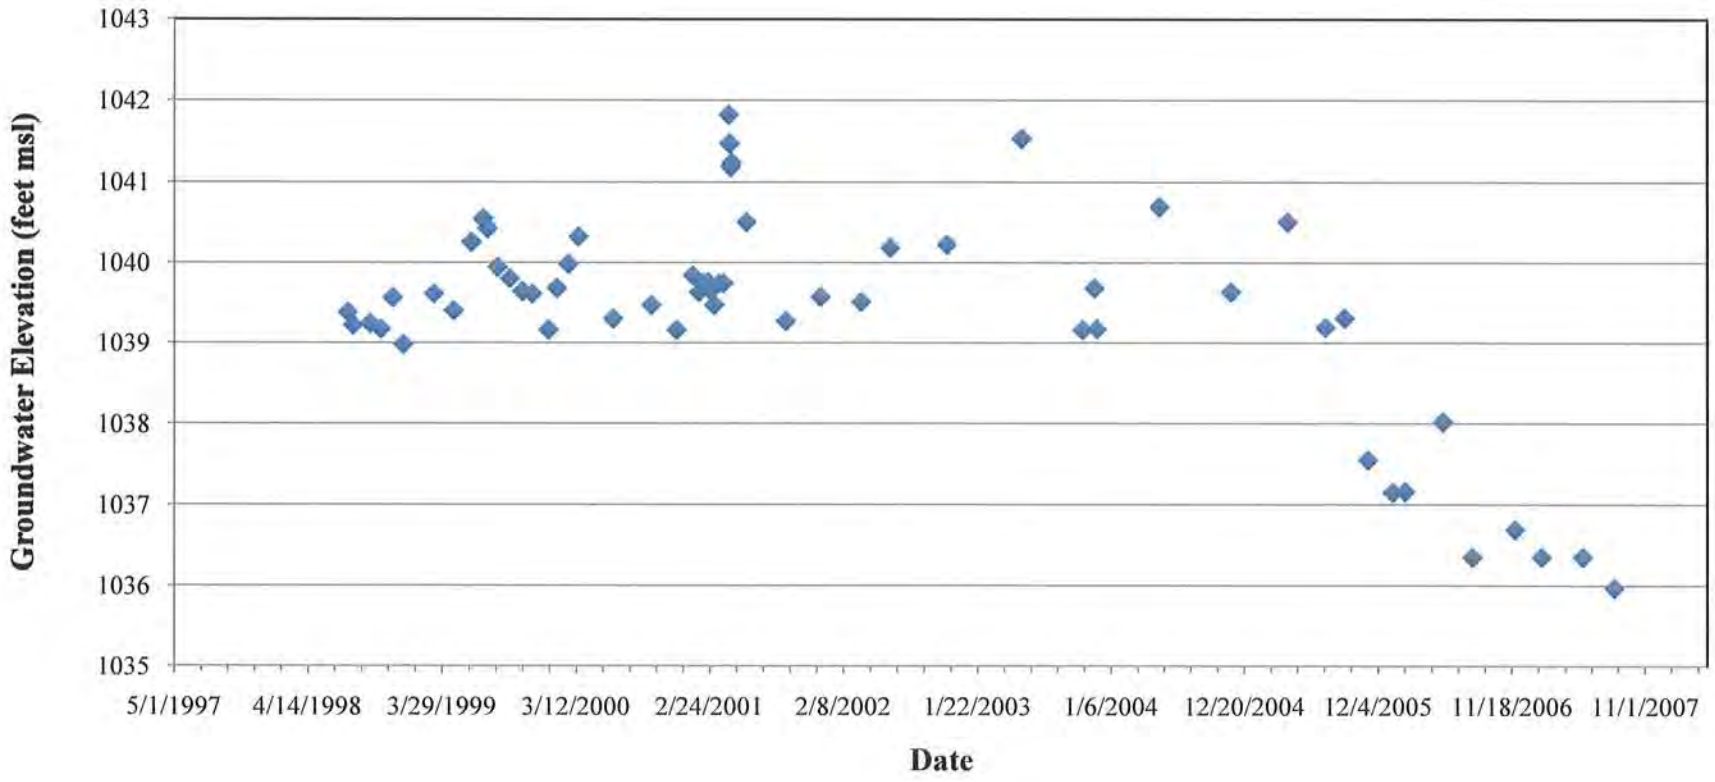
Groundwater Elevations in Well GM-25A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 19-29 Feet Below Ground Surface



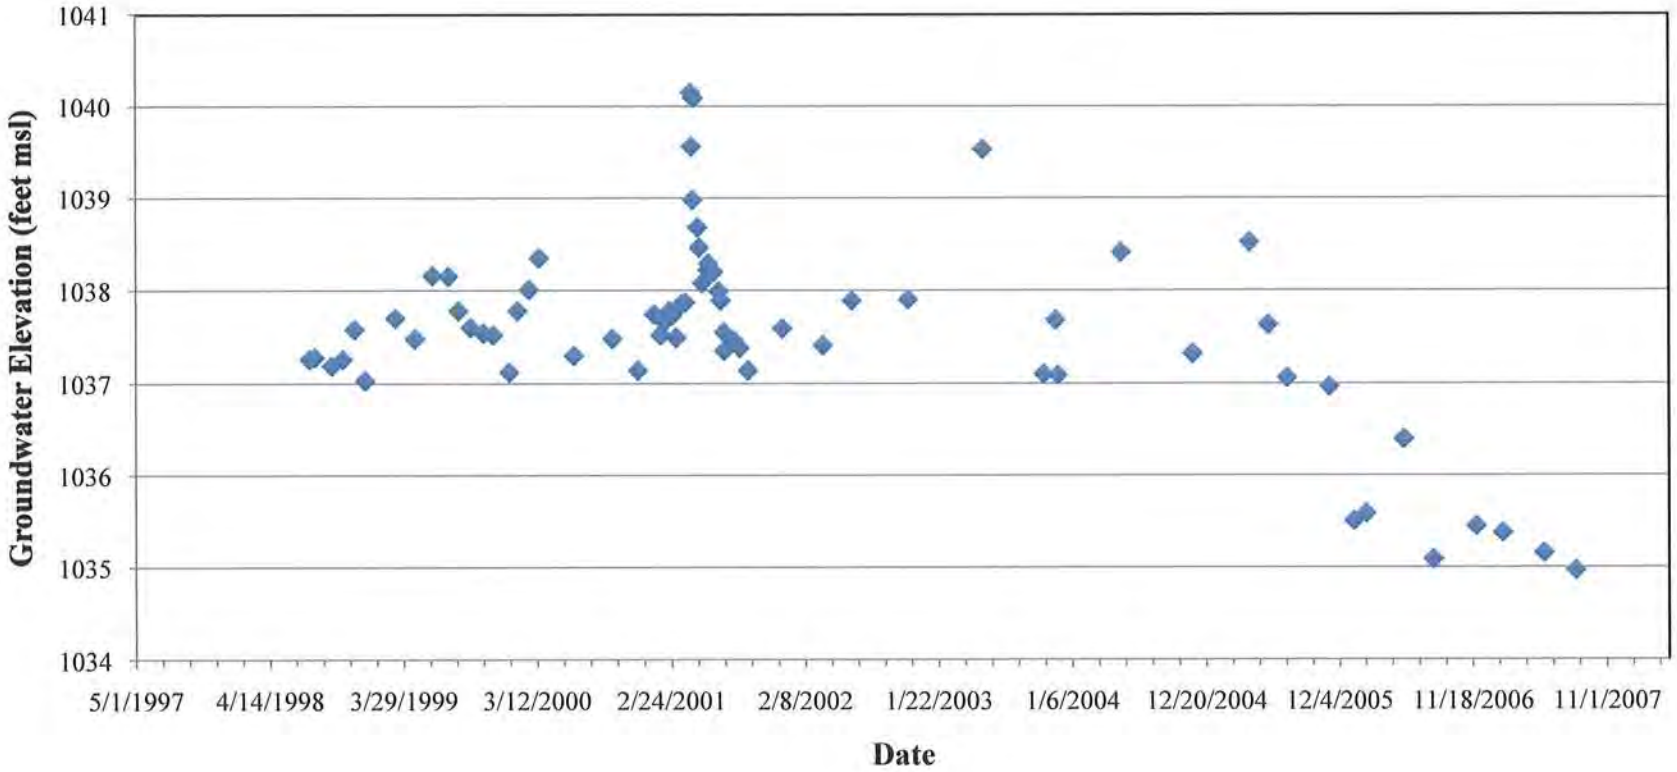
Groundwater Elevations in Well GM-25B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 98-108 Feet Below Ground Surface



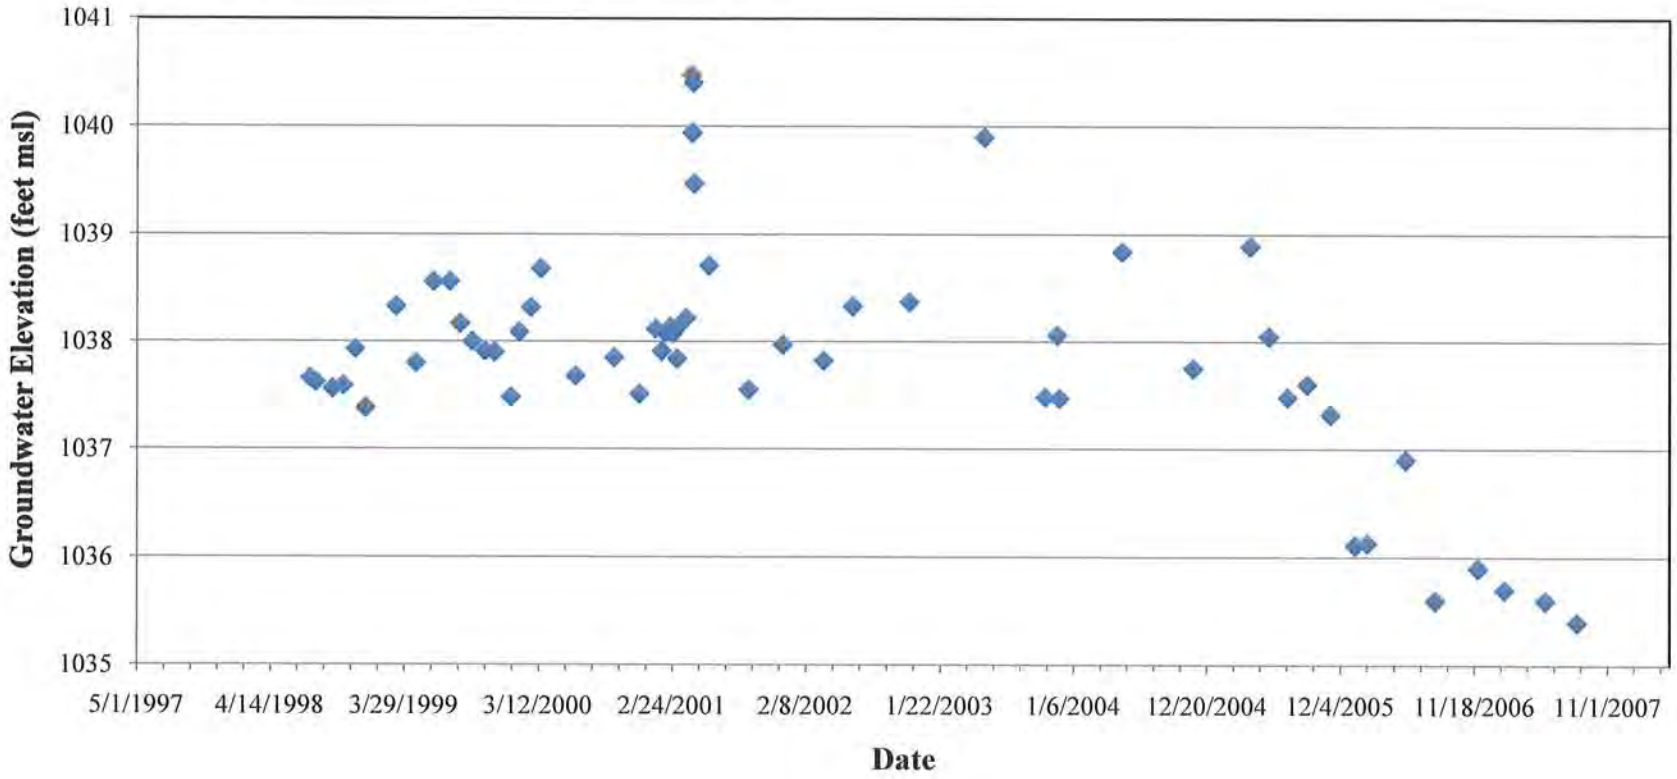
Groundwater Elevations in Well GM-25C
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 206-216 Feet Below Ground Surface



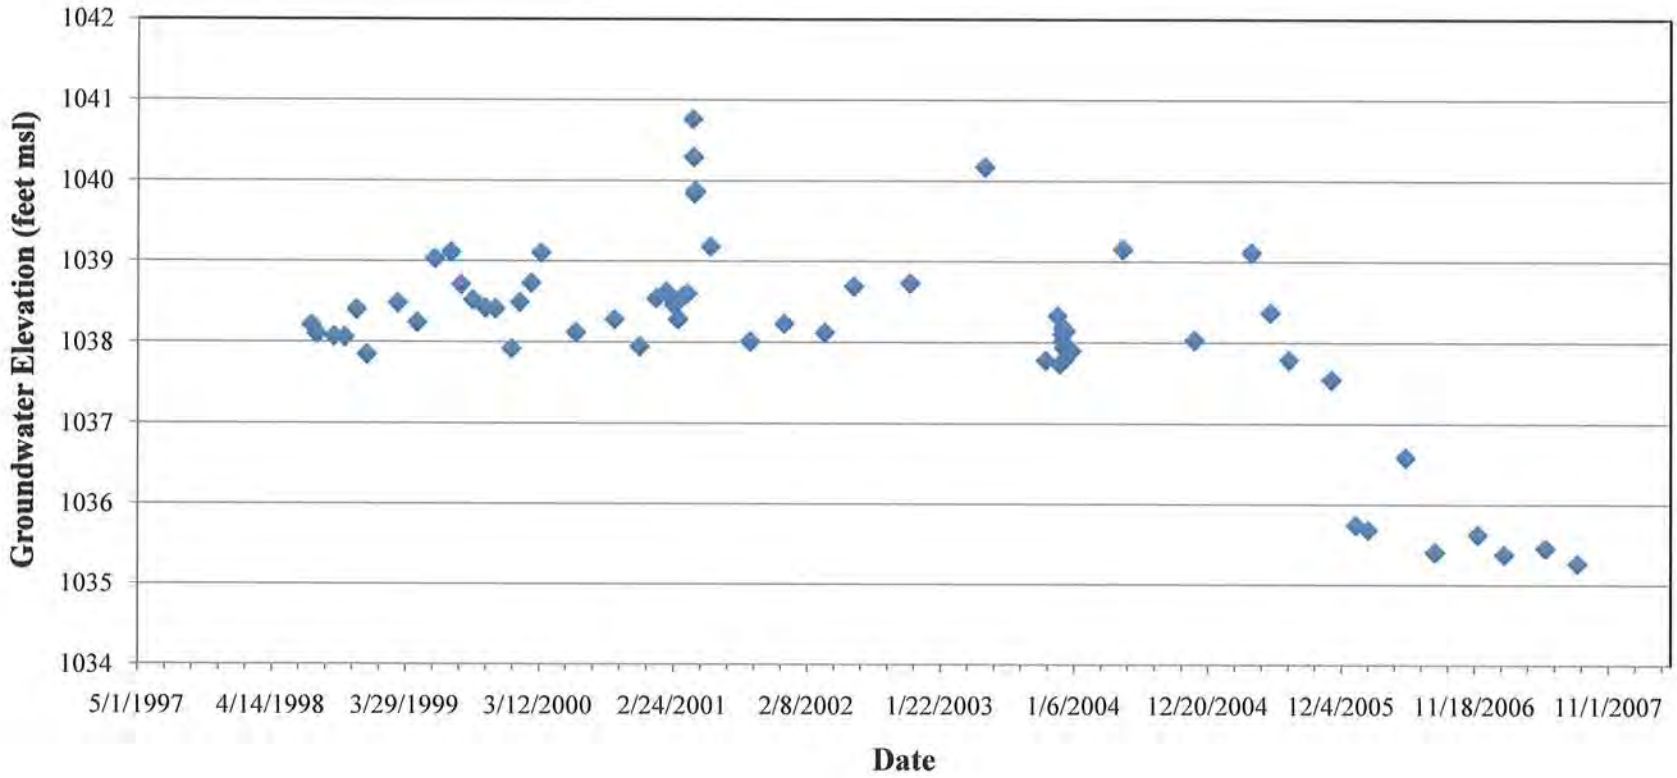
Groundwater Elevations in Well GM-26A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 30-40 Feet Below Ground Surface



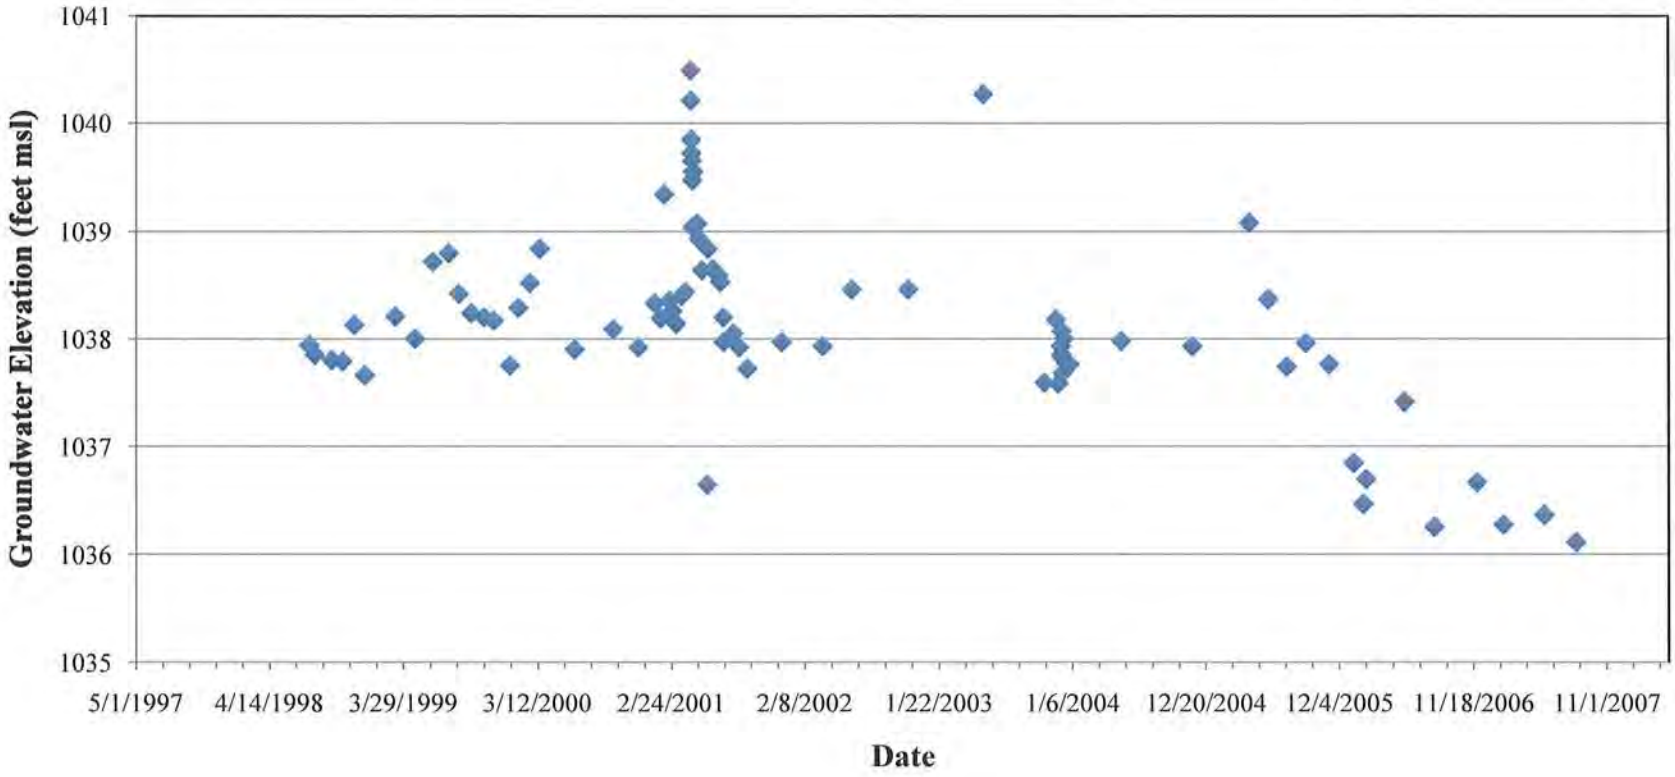
Groundwater Elevations in Well GM-26B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 101-111 Feet Below Ground Surface



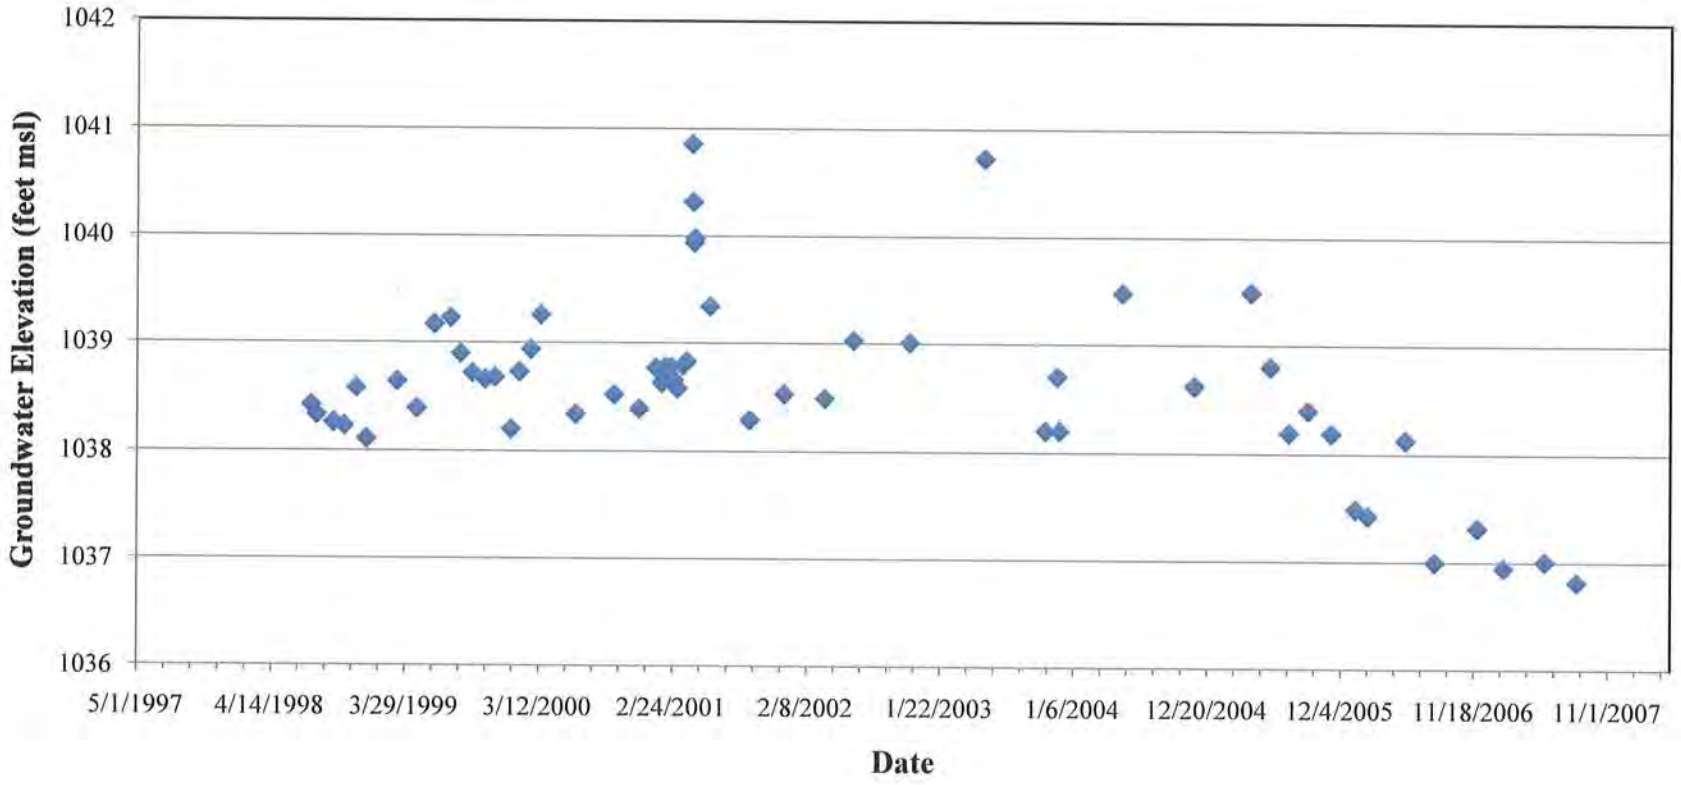
Groundwater Elevations in Well GM-26C
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 160-170 Feet Below Ground Surface



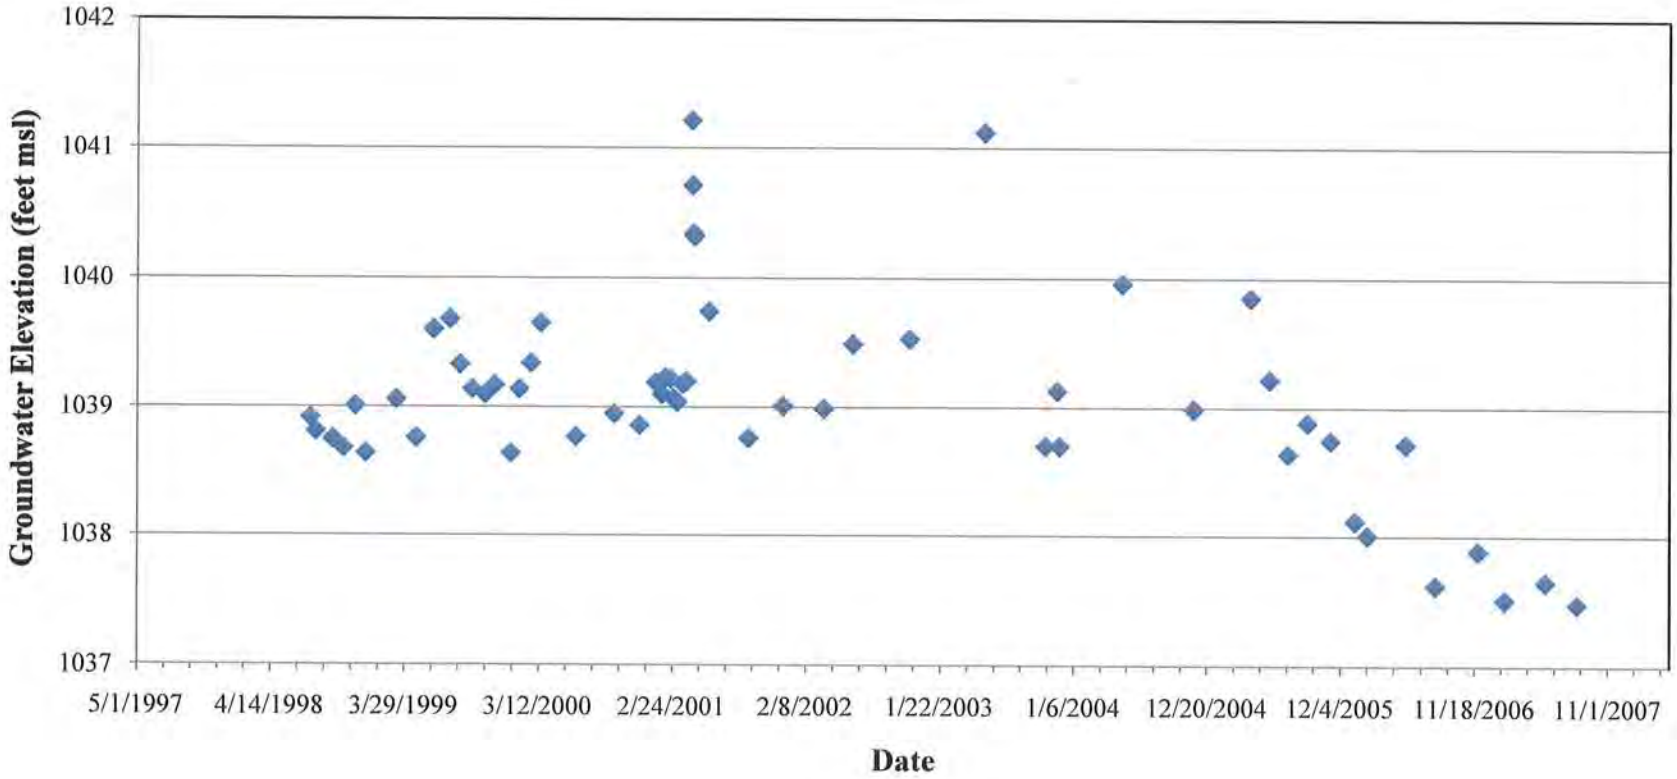
Groundwater Elevations in Well GM-27A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 30-40 Feet Below Ground Surface



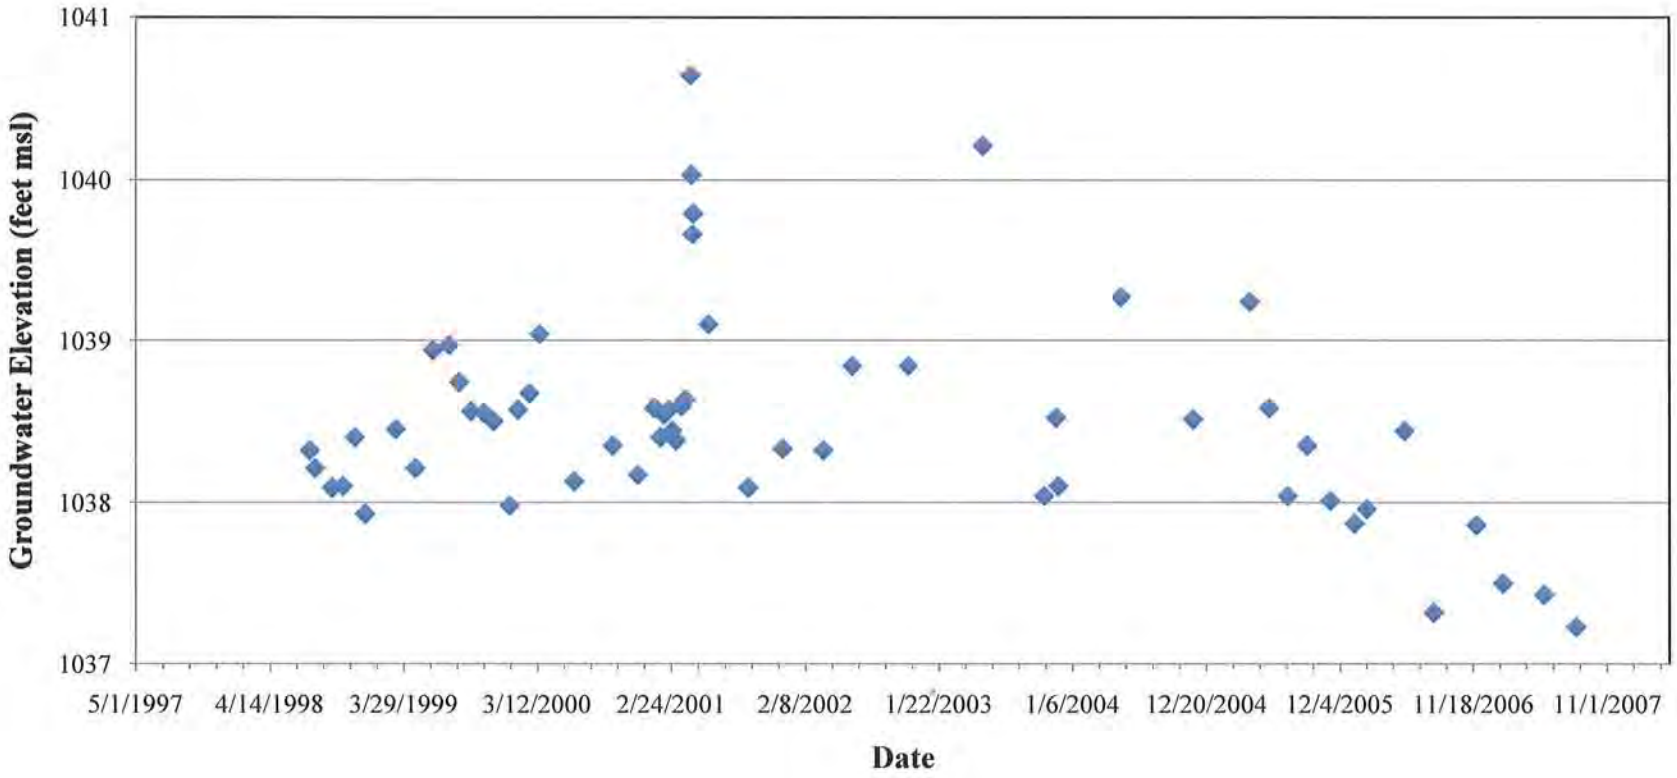
Groundwater Elevations in Well GM-27B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 145-155 Feet Below Ground Surface



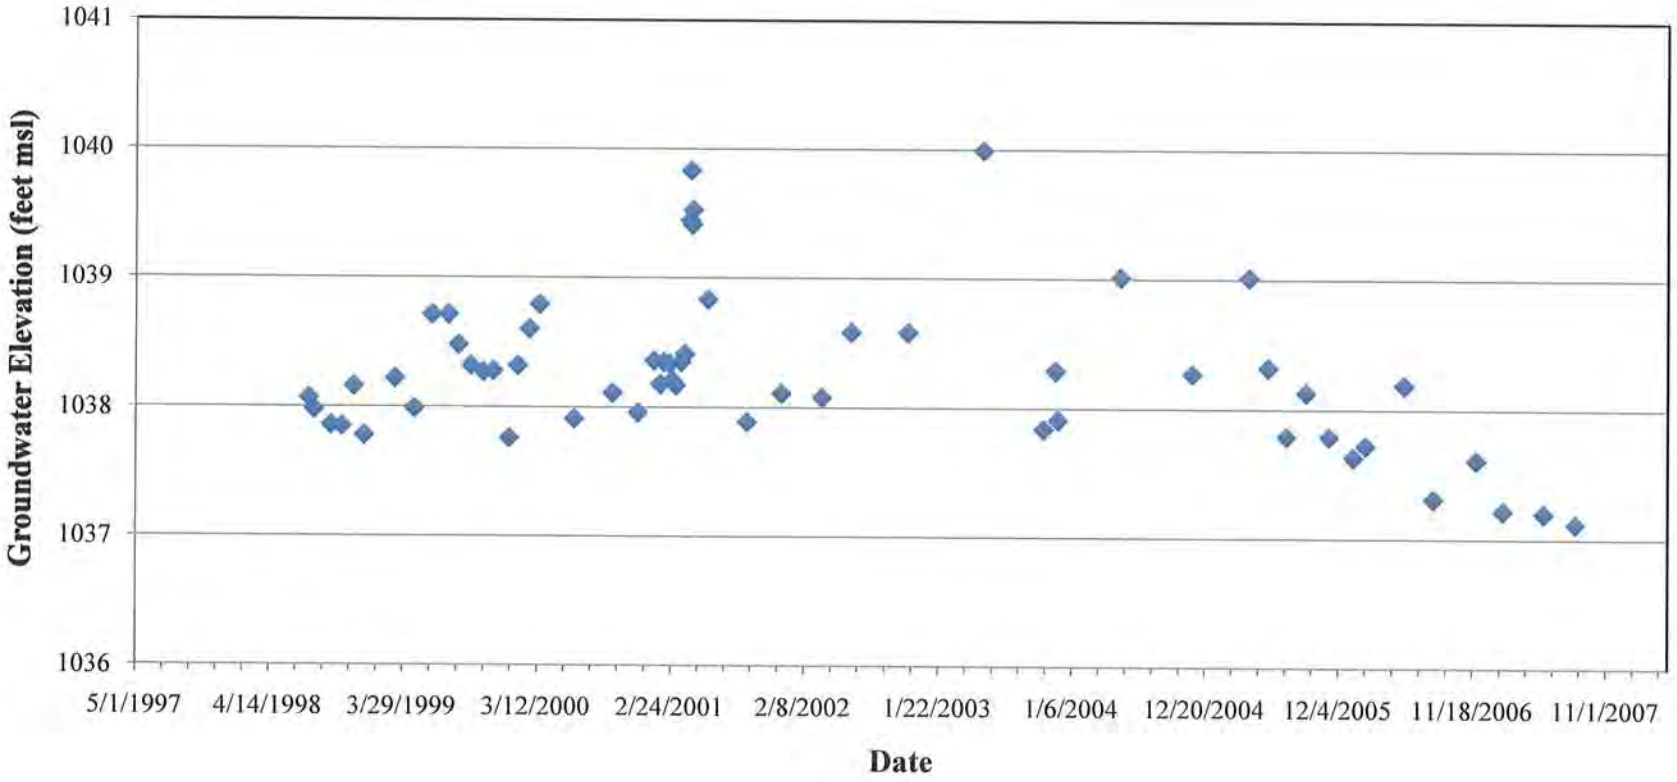
Groundwater Elevations in Well GM-27C
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 210-220 Feet Below Ground Surface



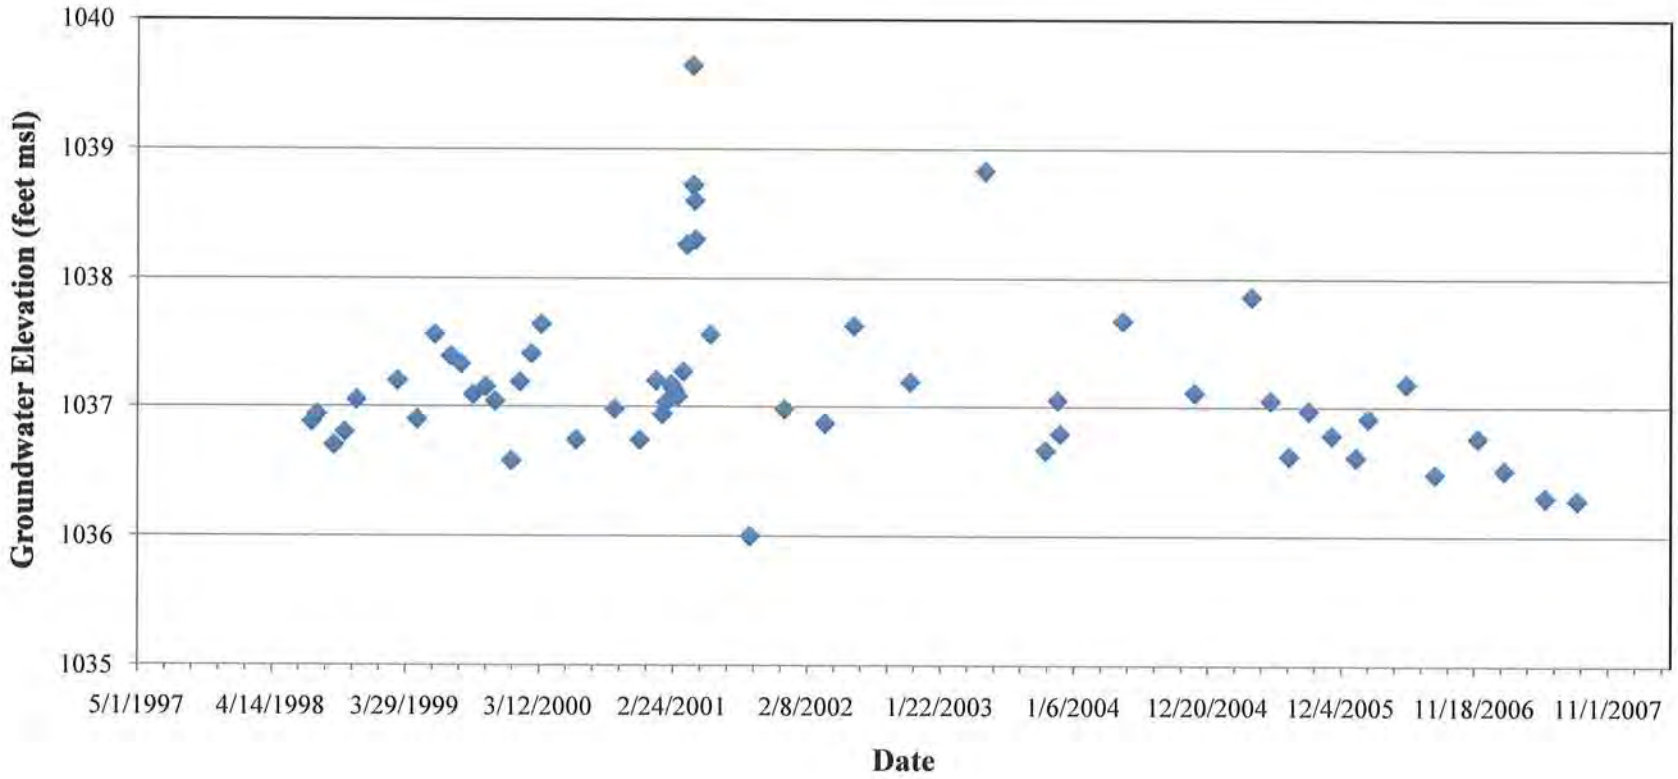
Groundwater Elevations in Well GM-28A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 40-50 Feet Below Ground Surface



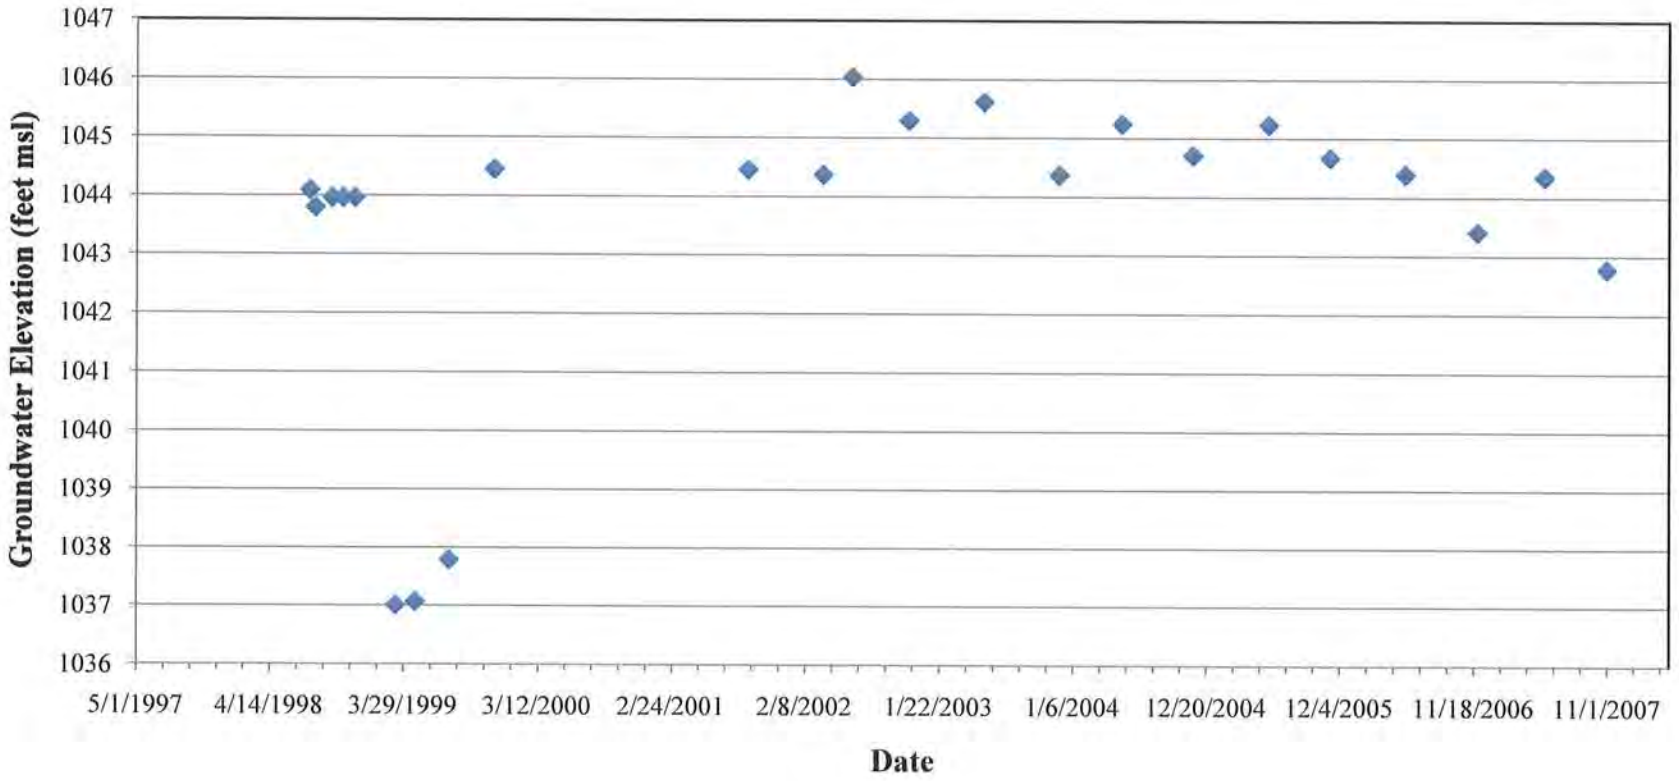
Groundwater Elevations in Well GM-28B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 124.5-129.5 Feet Below Ground Surface



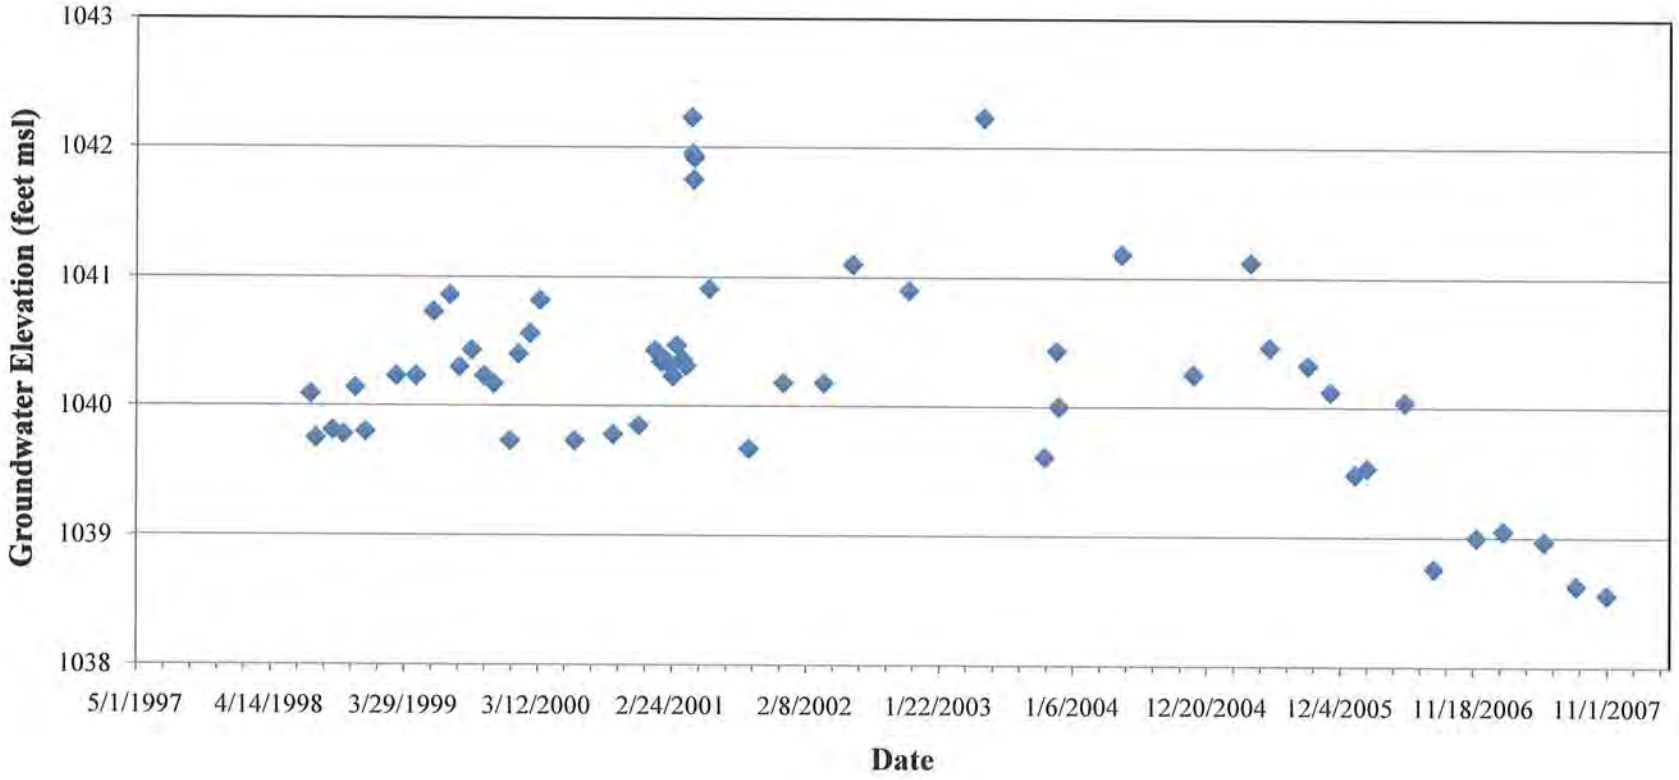
Groundwater Elevations in Well GM-29
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 55-65 Feet Below Ground Surface



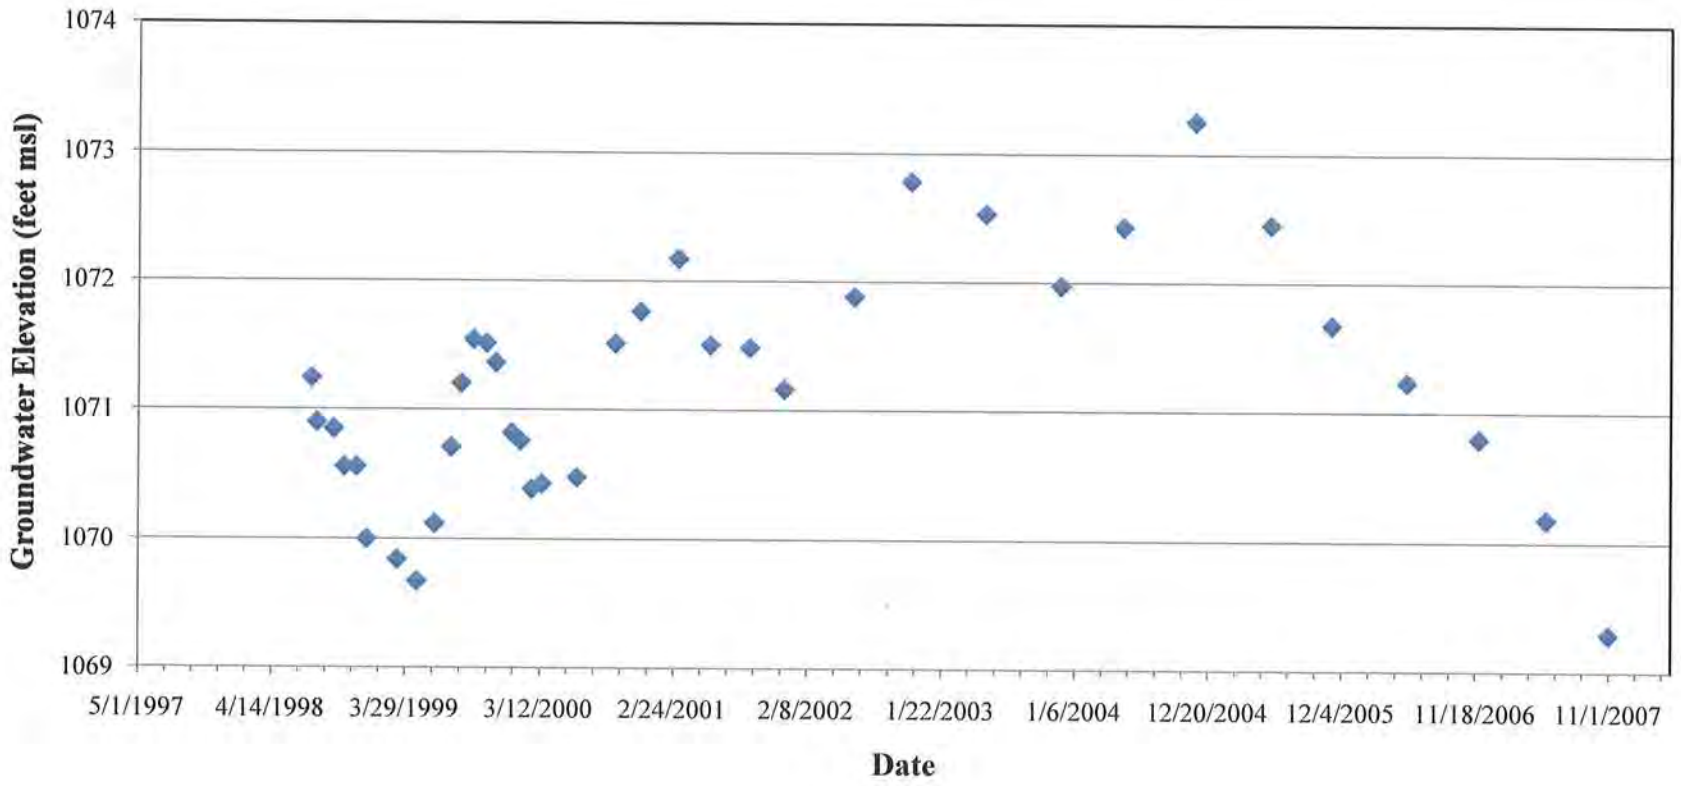
Groundwater Elevations in Well GM-30
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 75-85 Feet Below Ground Surface



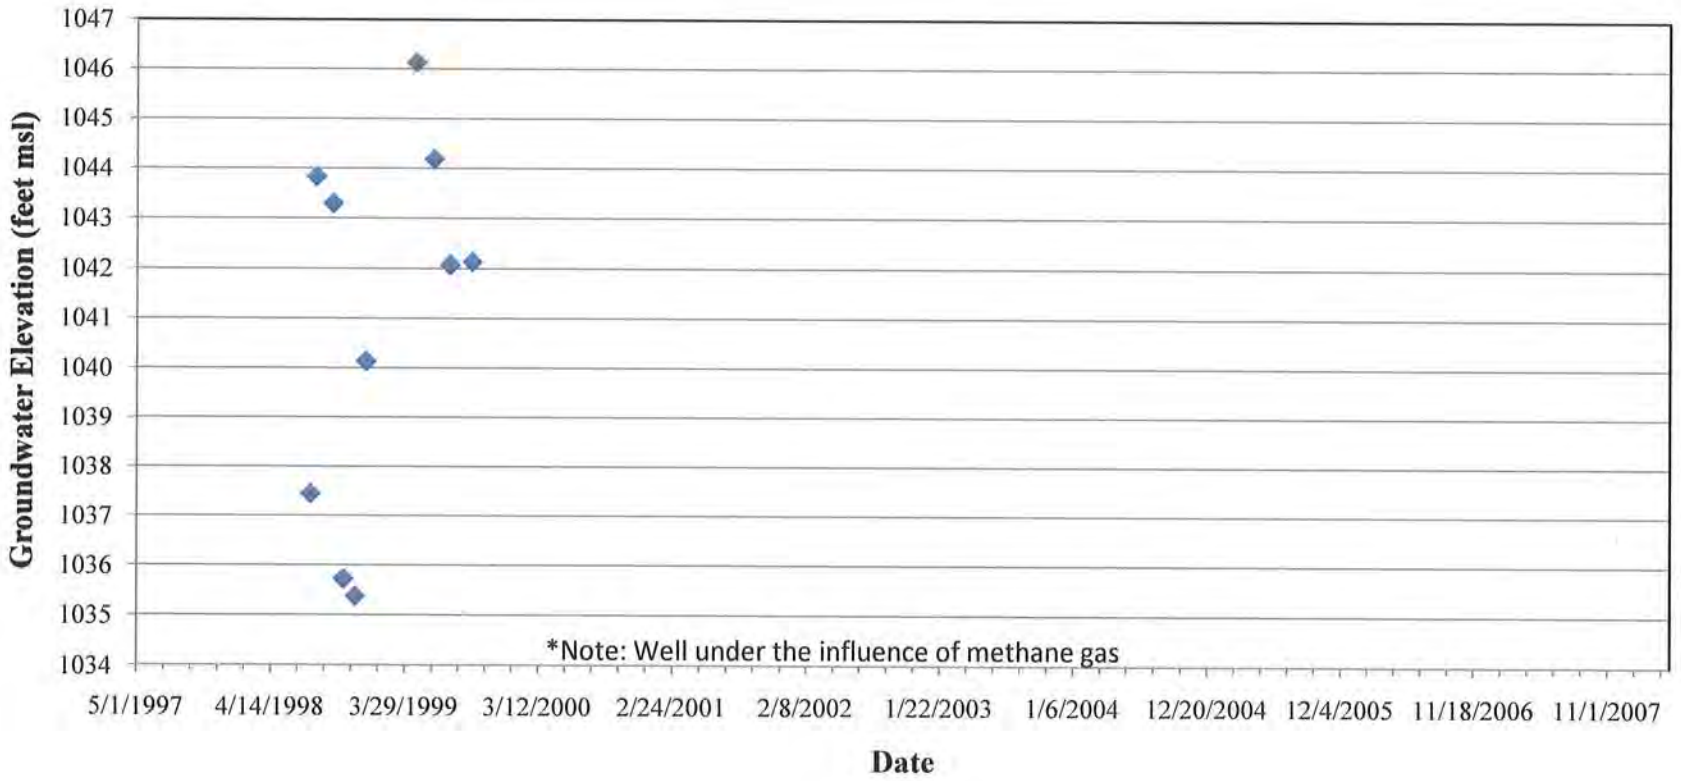
Groundwater Elevations in Well GM-31
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 105-115 Feet Below Ground Surface



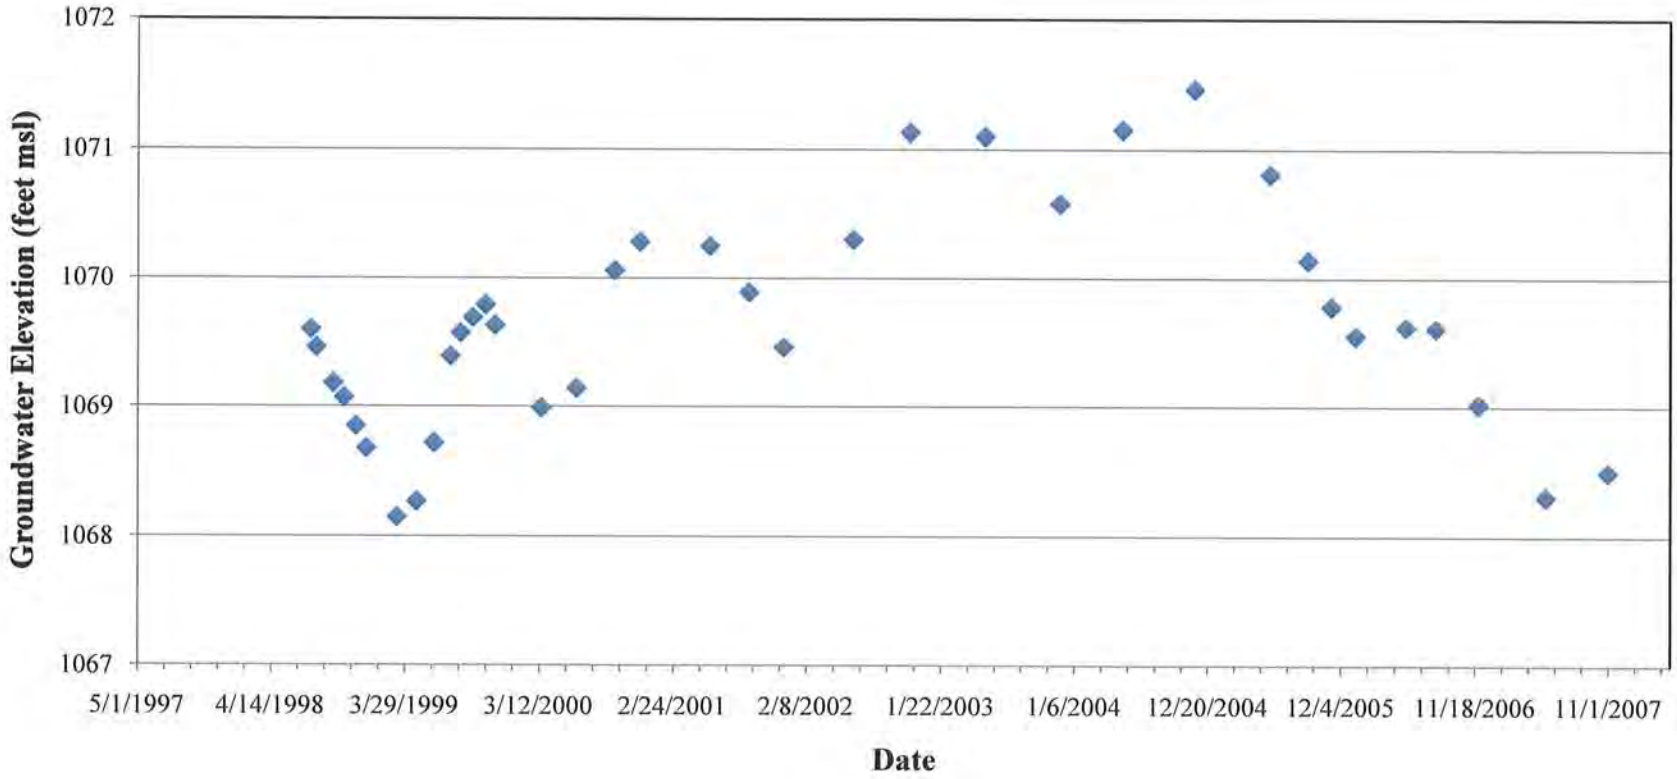
Groundwater Elevations in Well GM-32
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 135-145 Feet Below Ground Surface



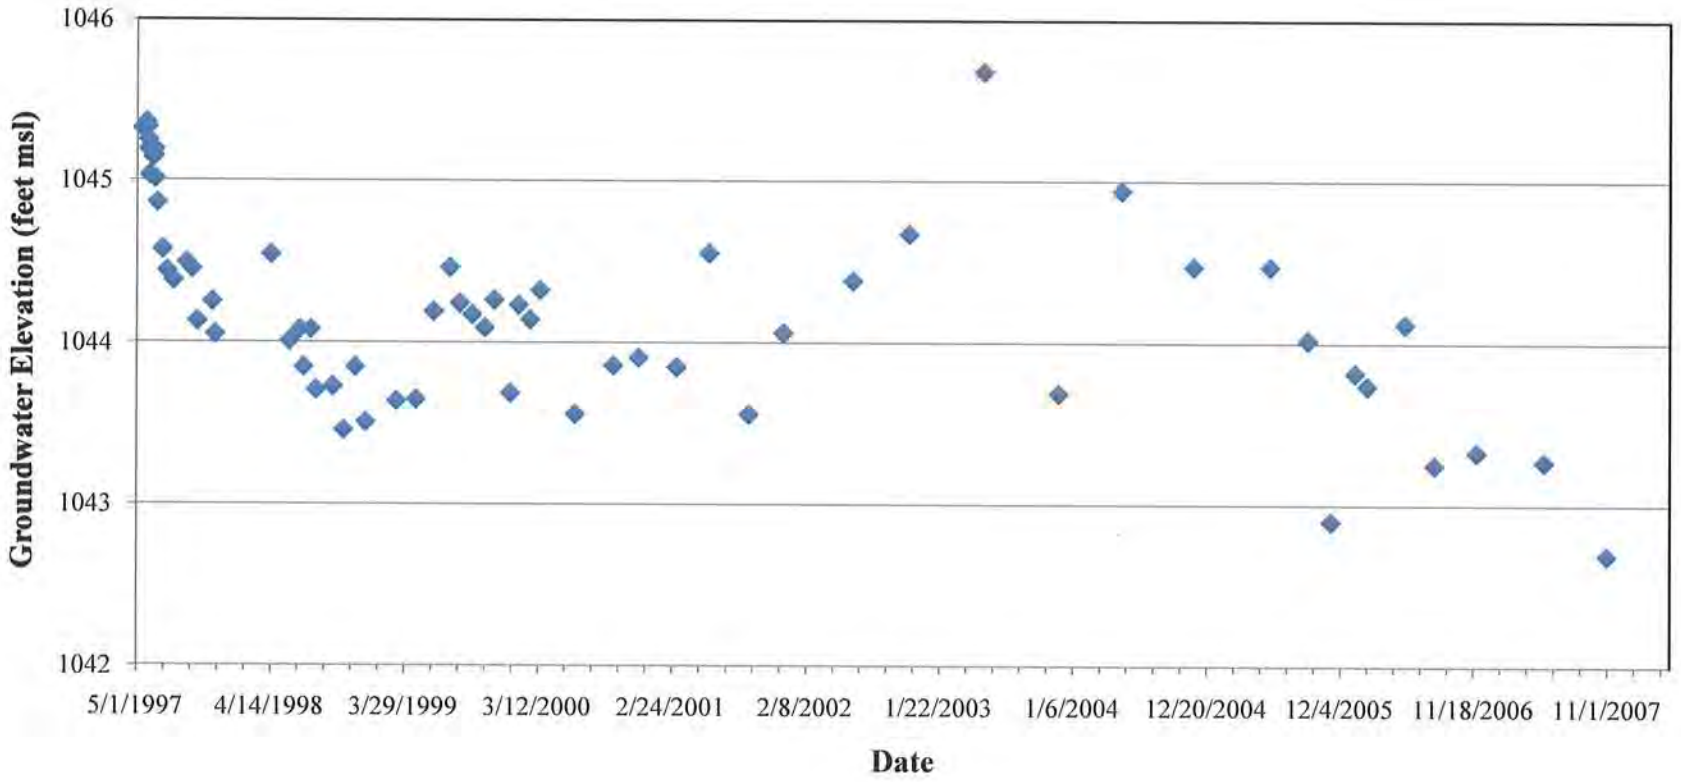
Groundwater Elevations in Well GM-33
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 74-89 Feet Below Ground Surface



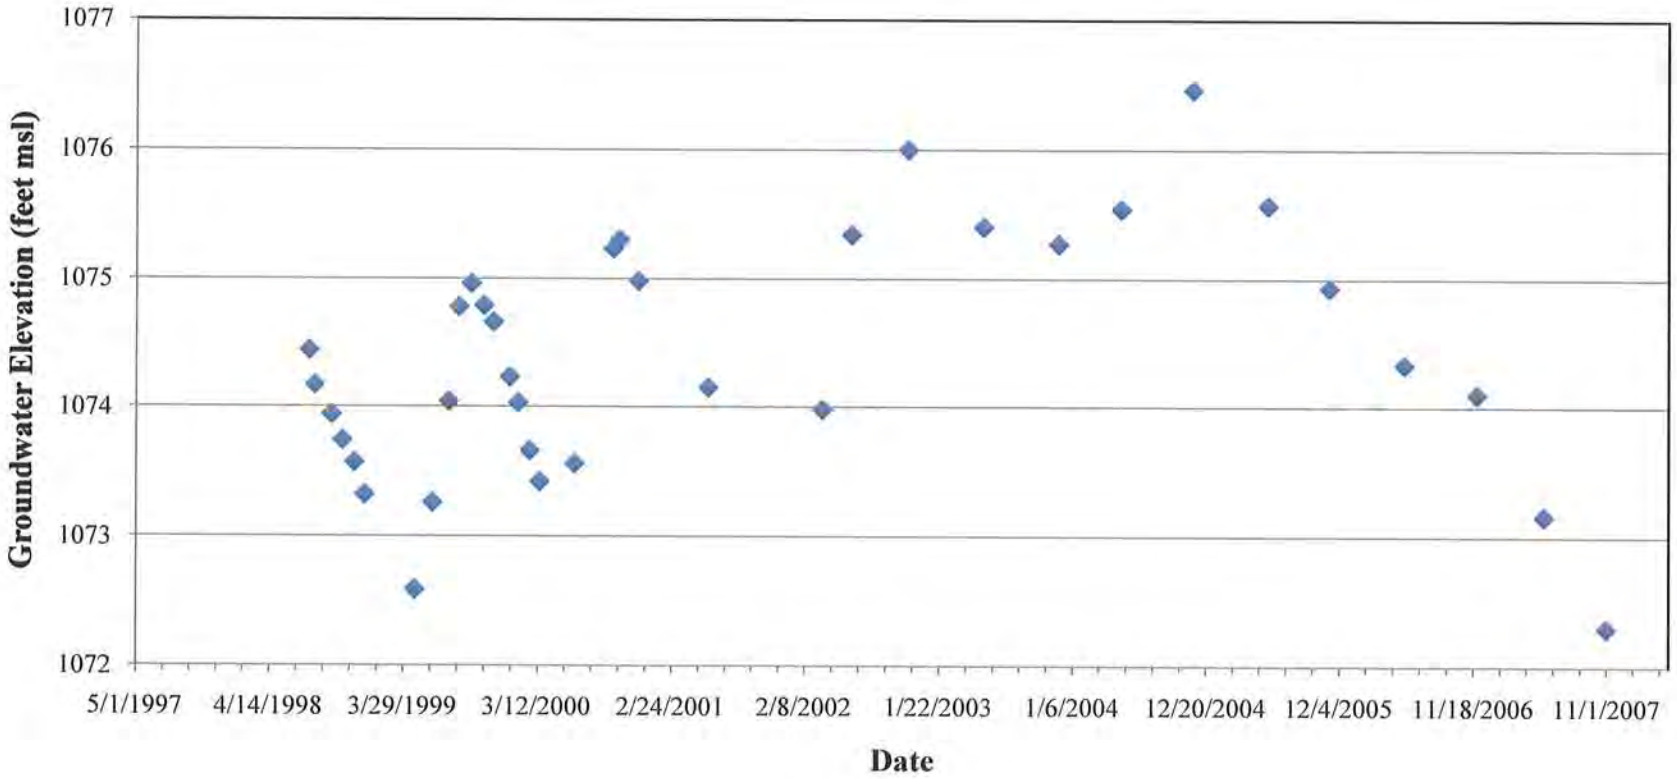
Groundwater Elevations in Well GM-34A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 30-40 Feet Below Ground Surface



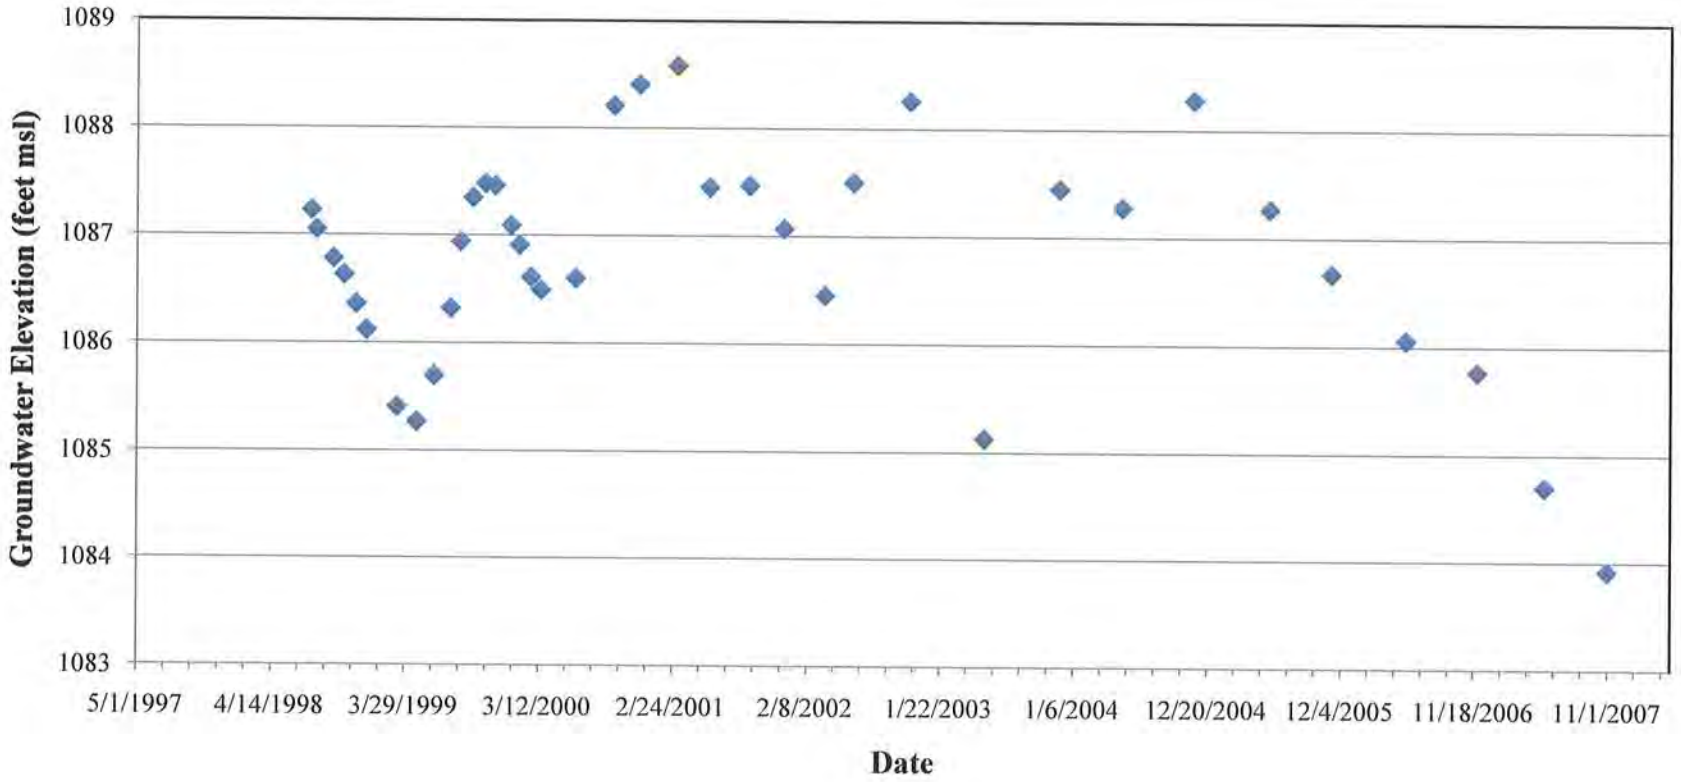
Groundwater Elevations in Well GM-34B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 85-95 Feet Below Ground Surface



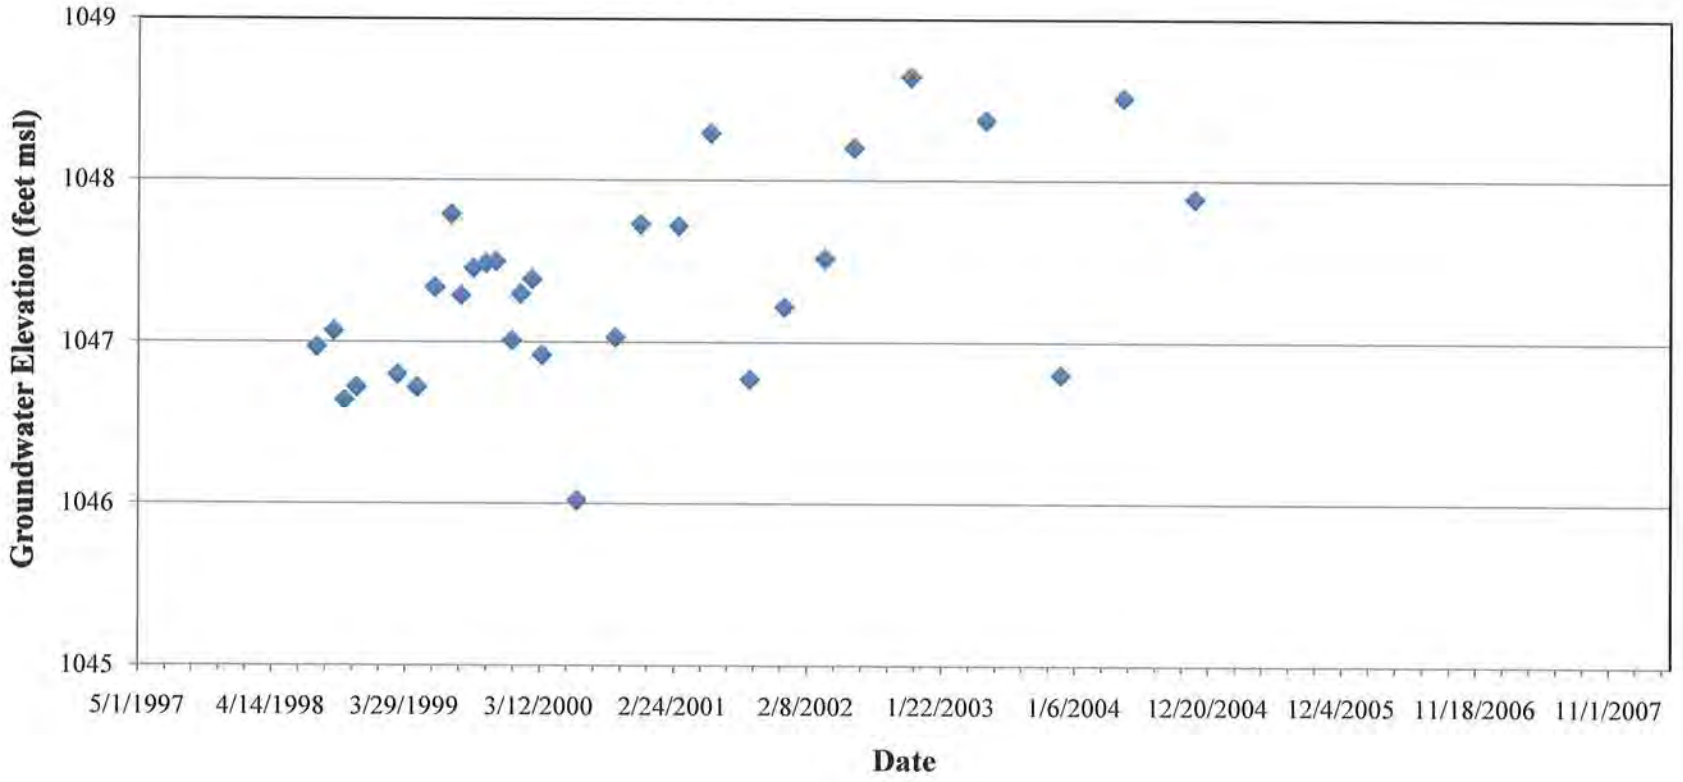
Groundwater Elevations in Well GM-35
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 40-50 Feet Below Ground Surface



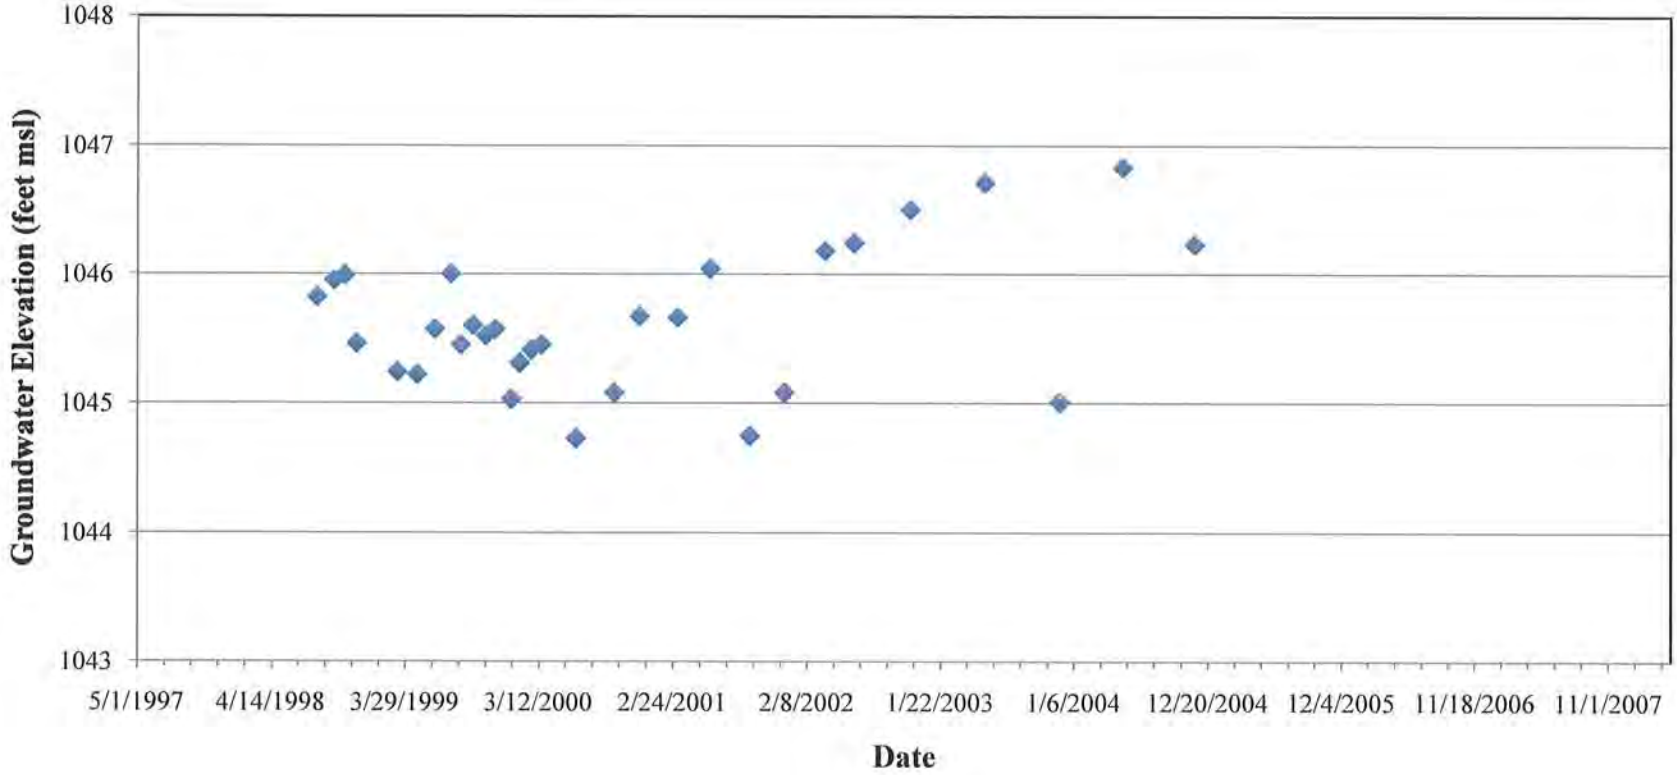
Groundwater Elevations in Well GM-36
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 95-105 Feet Below Ground Surface



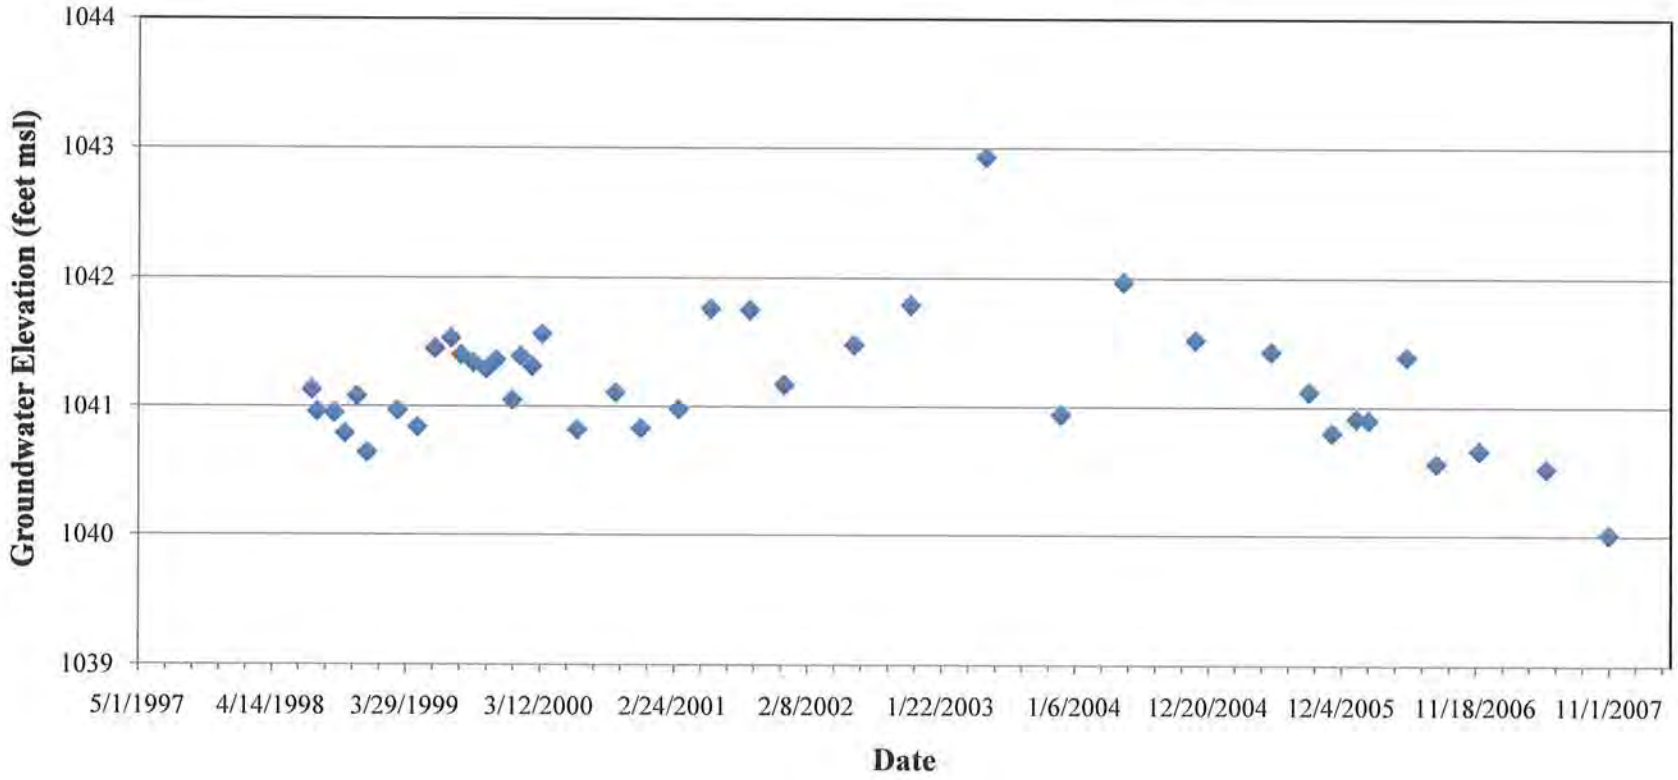
Groundwater Elevations in Well GM-37A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 144-154 Feet Below Ground Surface



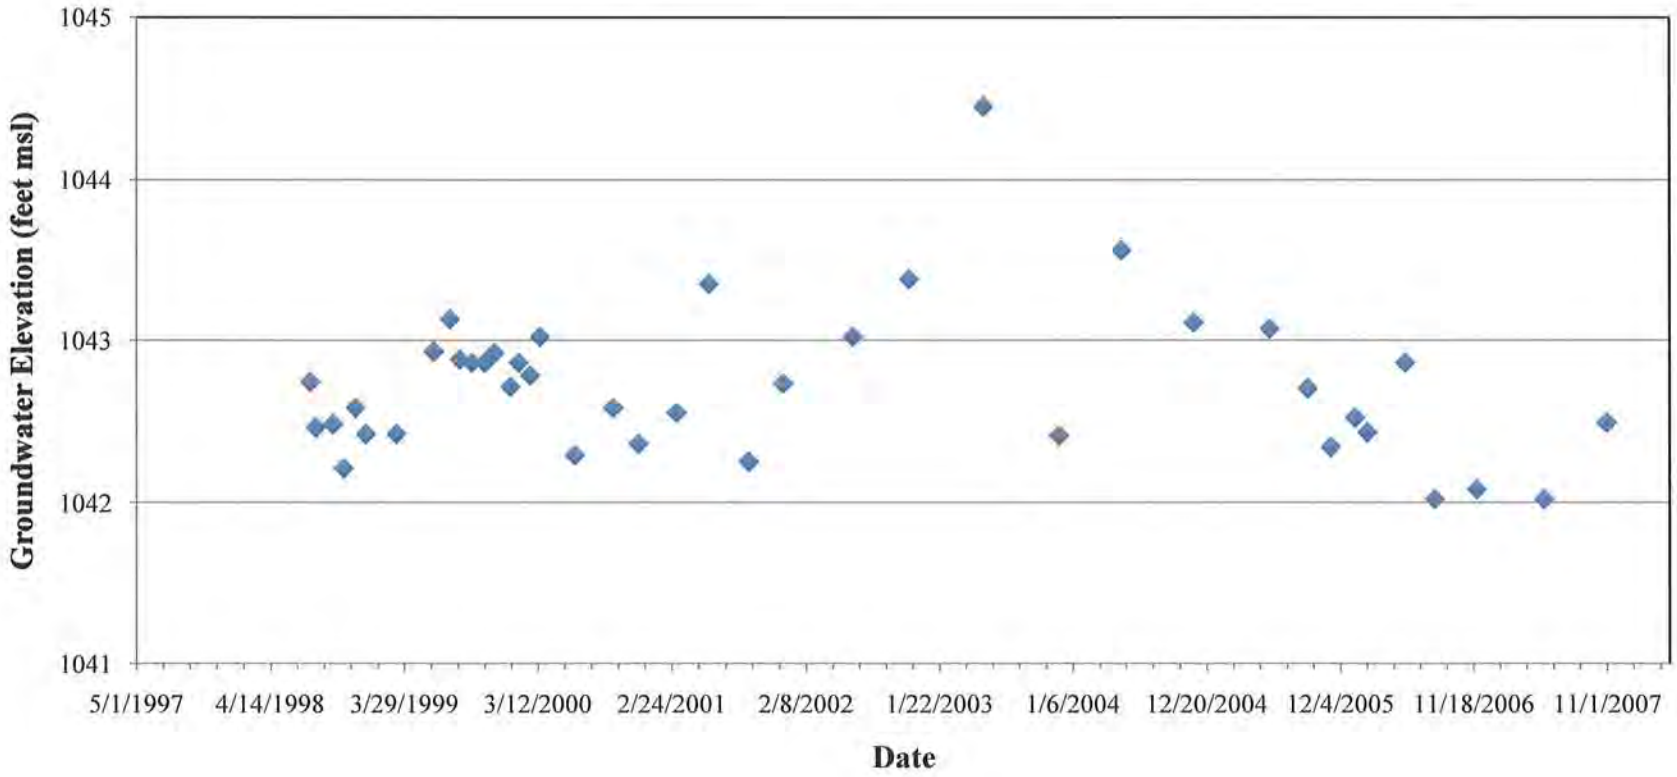
Groundwater Elevations in Well GM-37B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 328-338 Feet Below Ground Surface



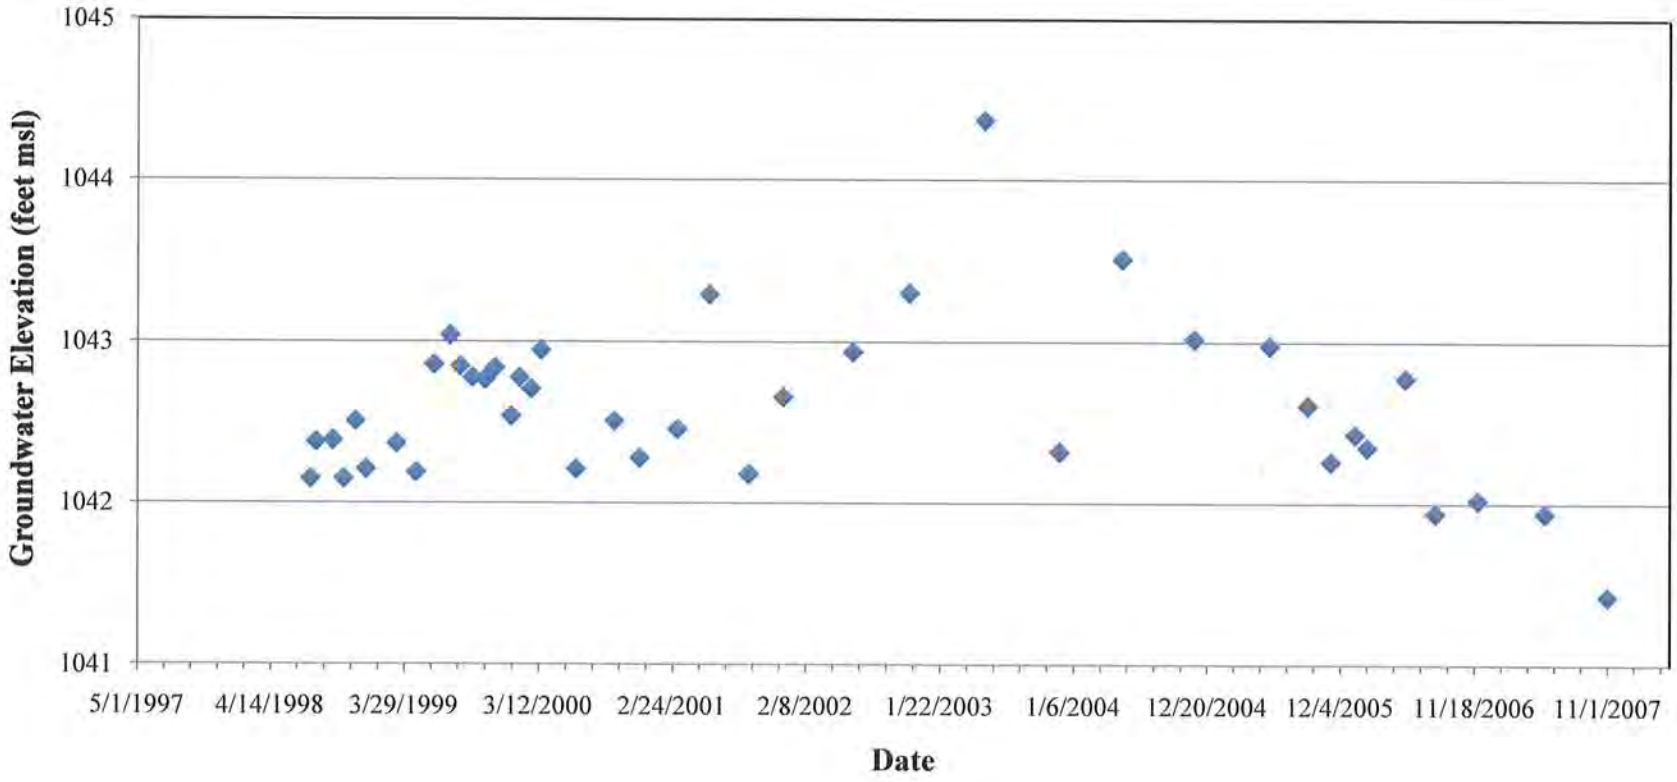
Groundwater Elevations in Well GM-38A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 95-105 Feet Below Ground Surface



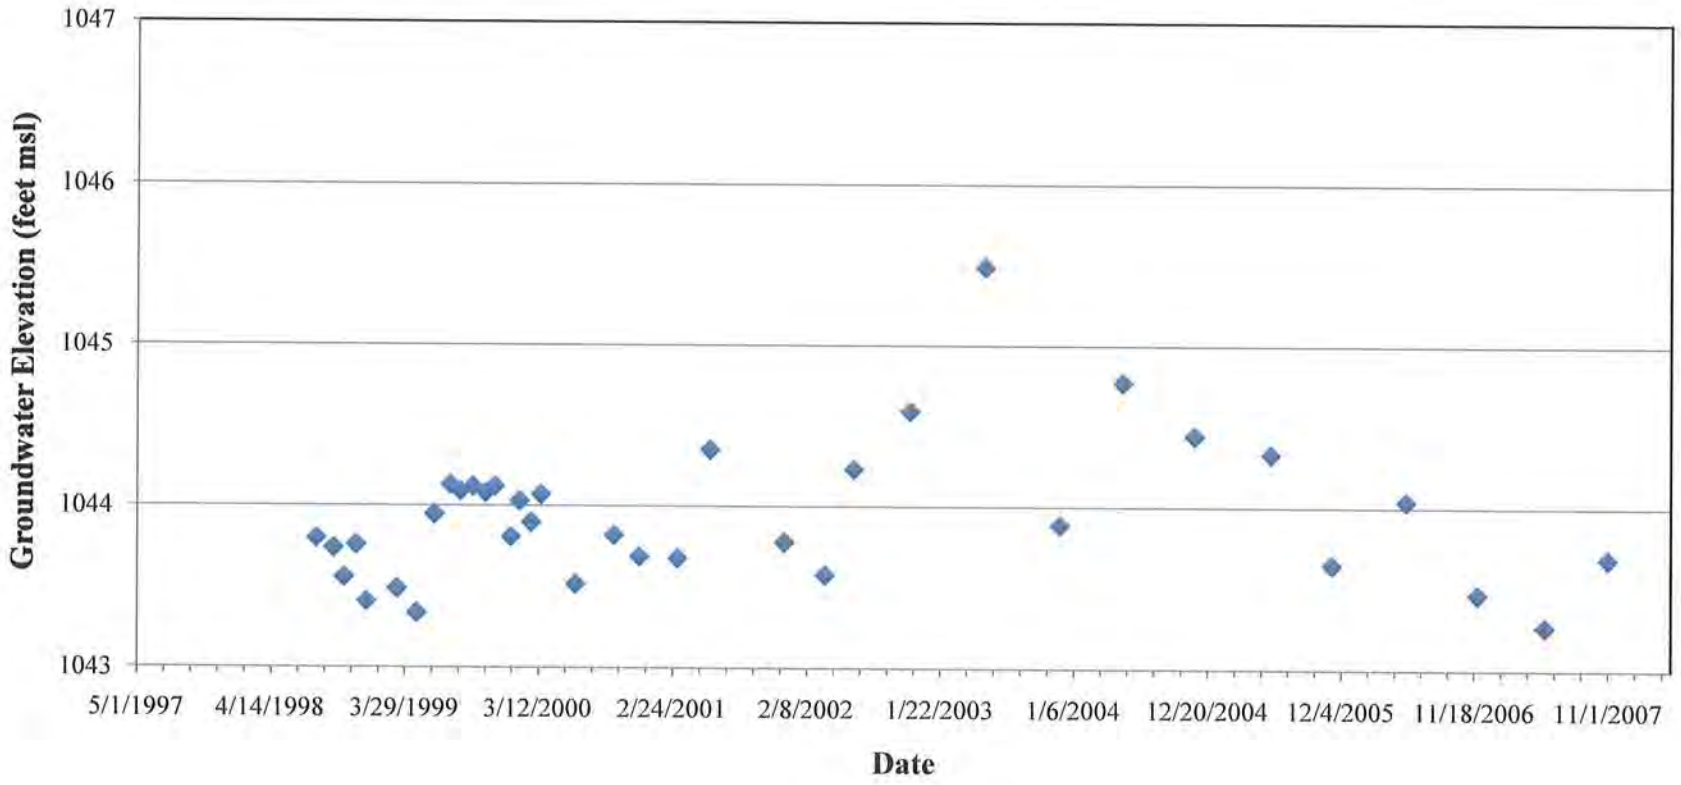
Groundwater Elevations in Well GM-38B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 160-170 Feet Below Ground Surface



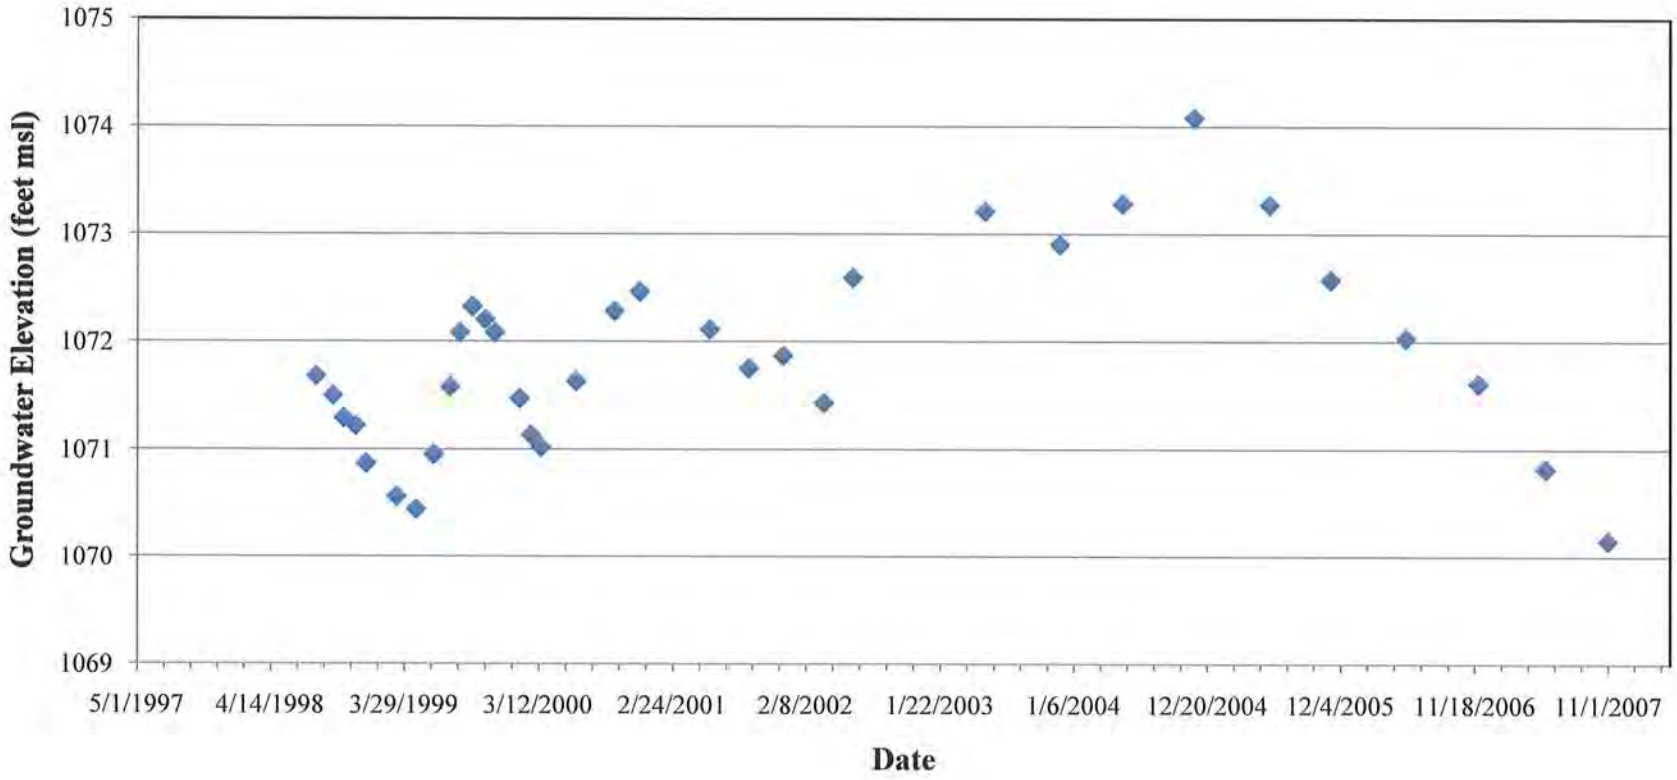
Groundwater Elevations in Well GM-38C
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 200-210 Feet Below Ground Surface



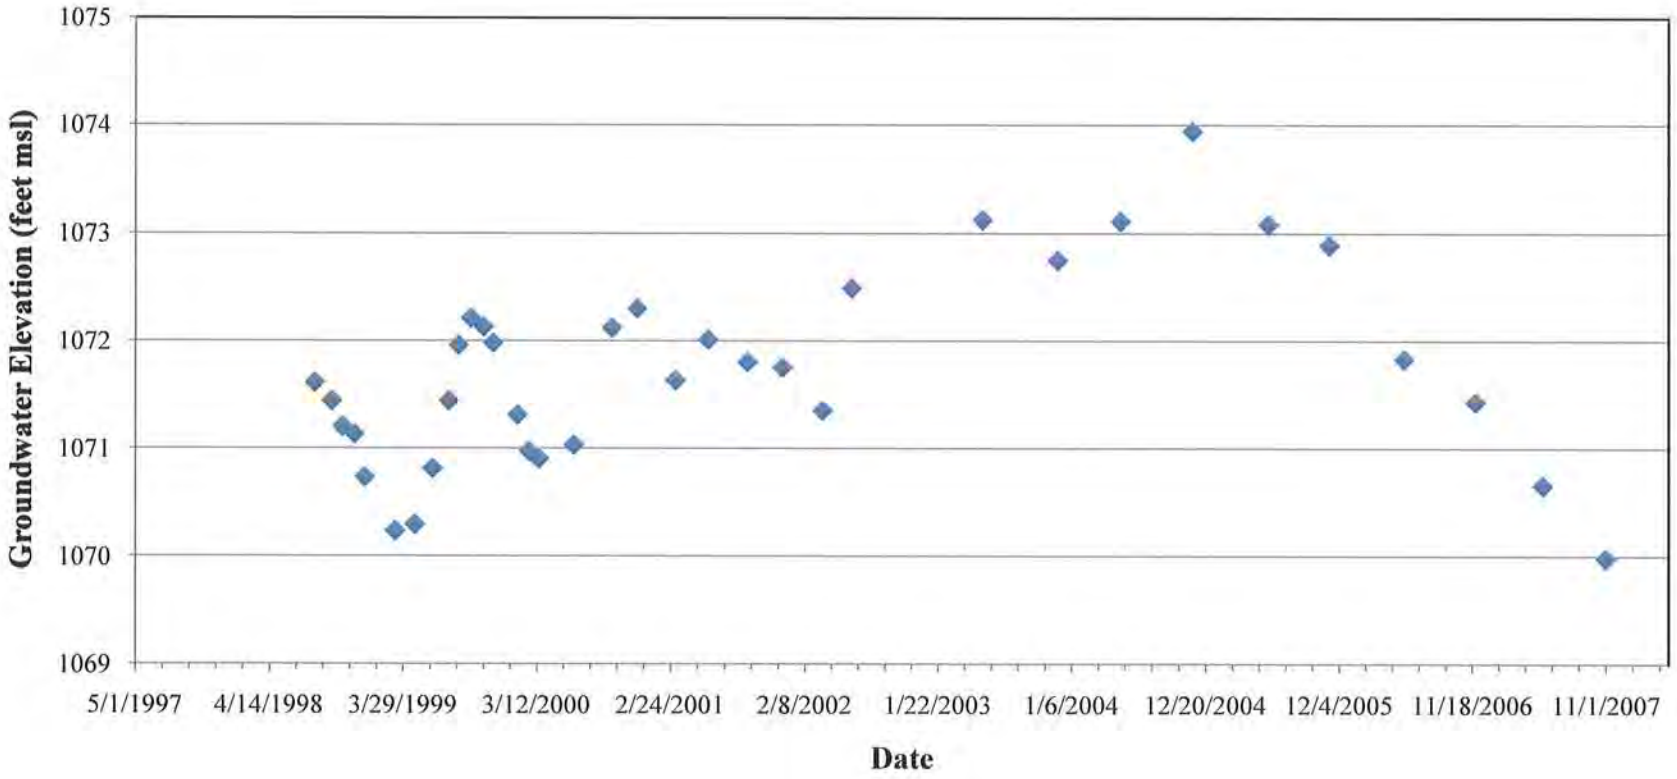
Groundwater Elevations in Well GM-39
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 85-95 Feet Below Ground Surface



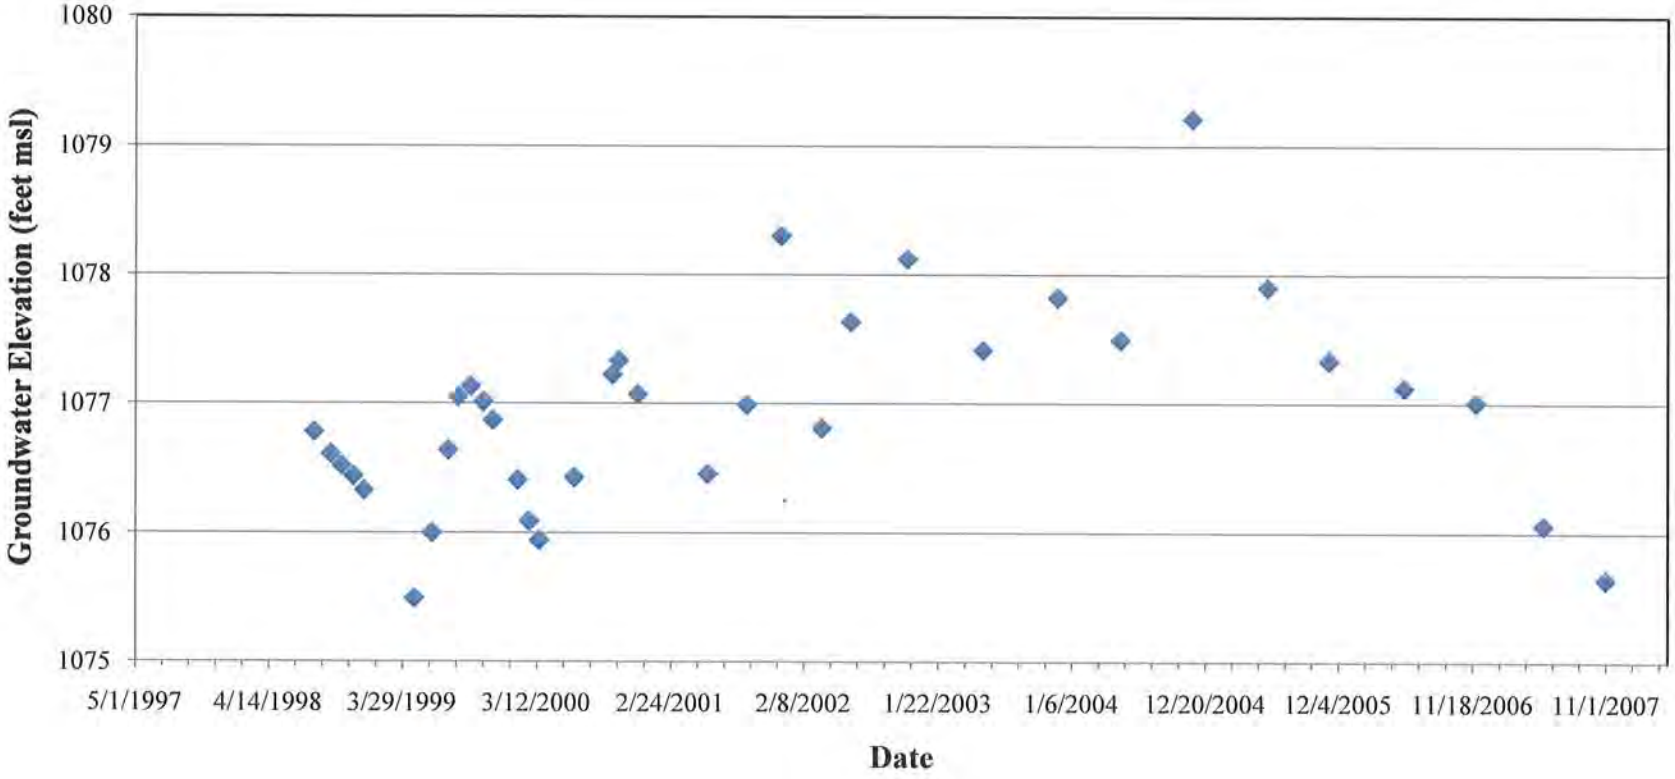
Groundwater Elevations in Well GM-40A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 75-85 Feet Below Ground Surface



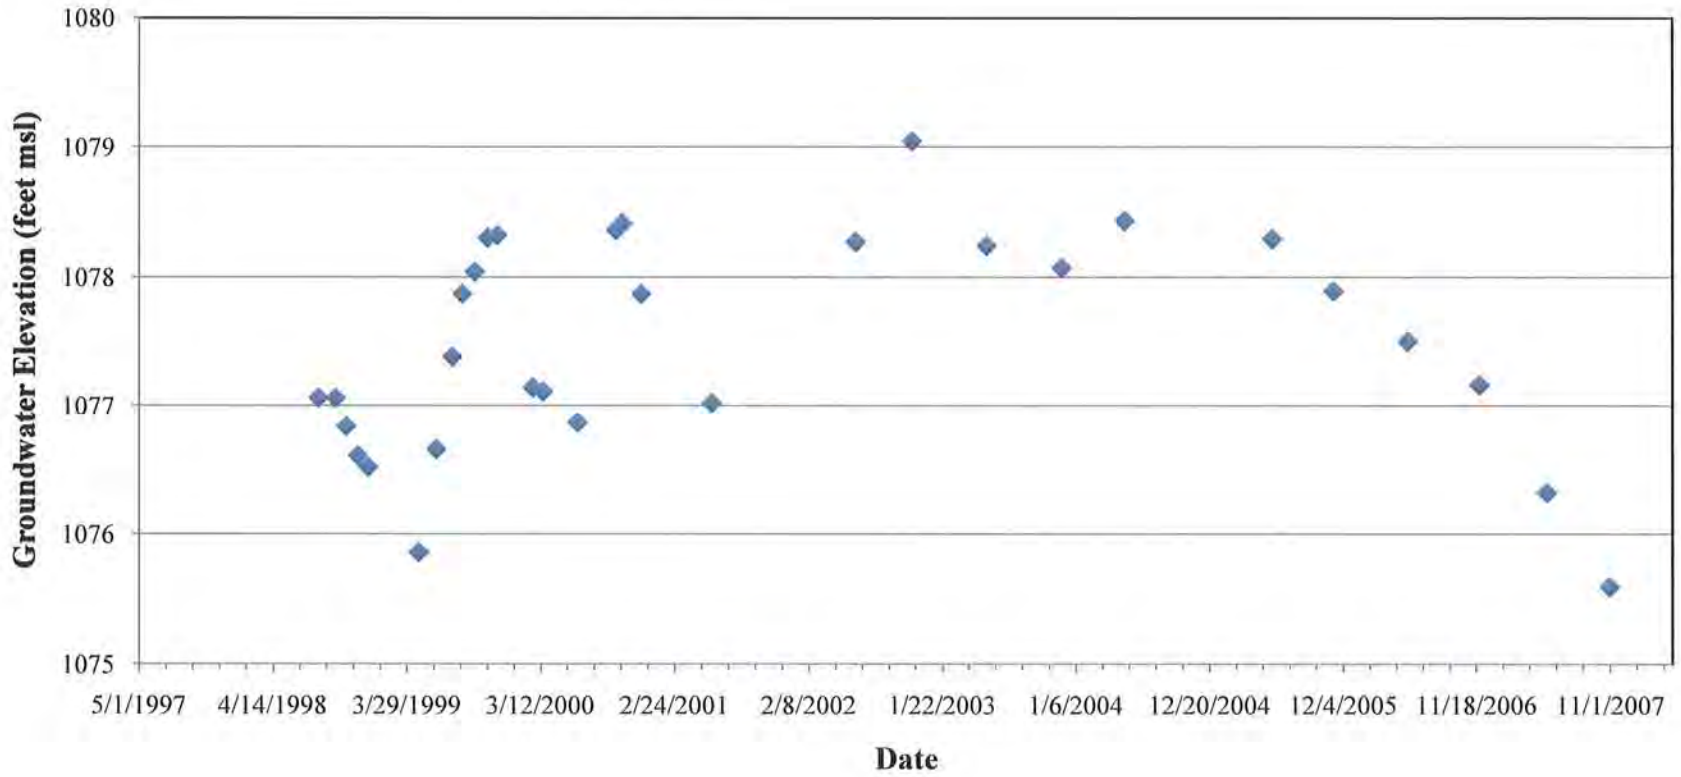
Groundwater Elevations in Well GM-40B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 120-130 Feet Below Ground Surface



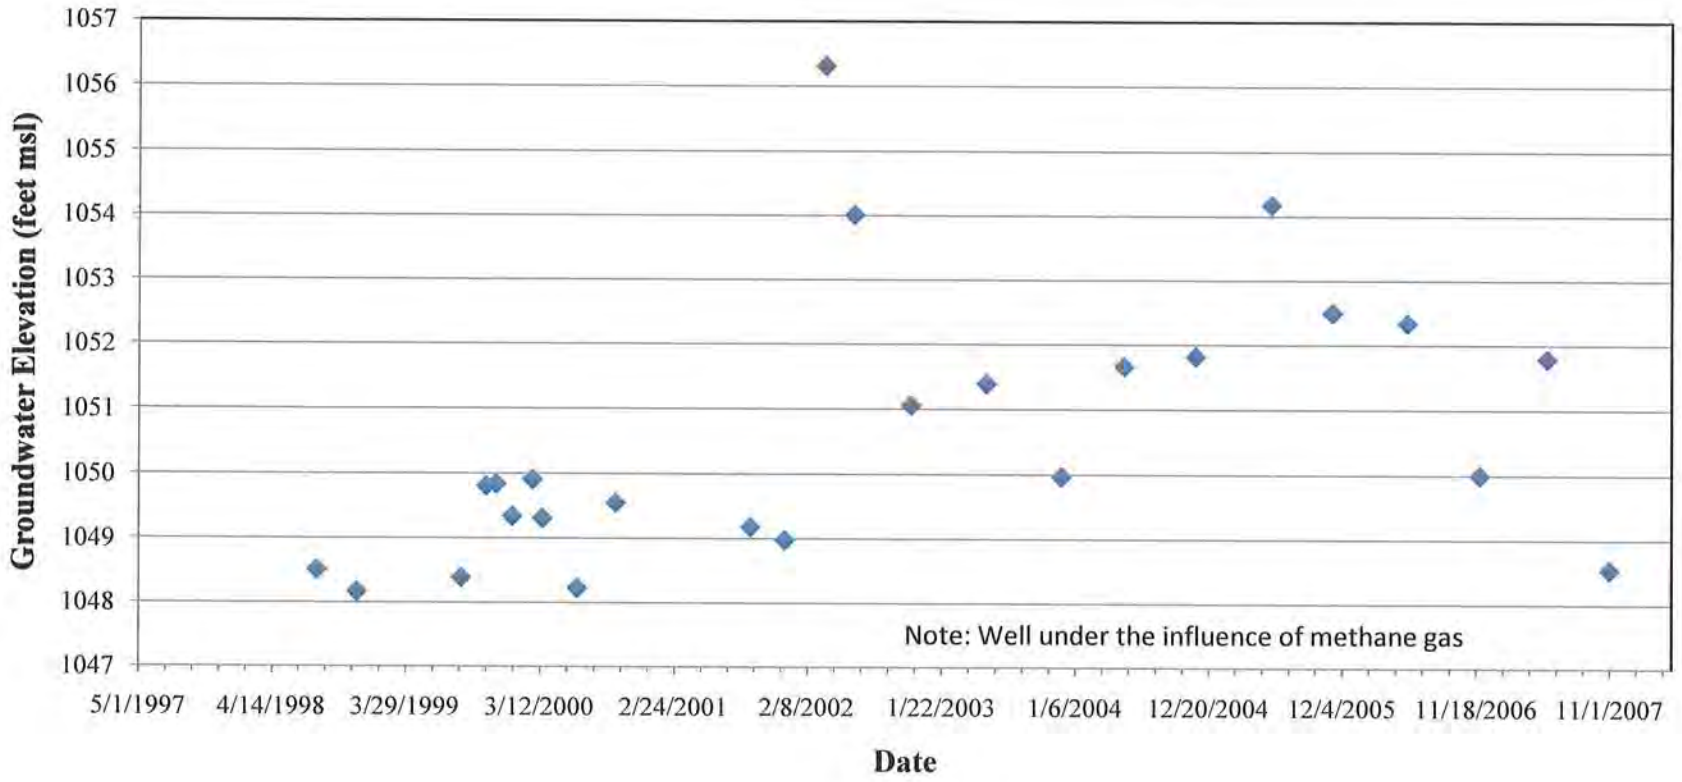
Groundwater Elevations in Well GM-41
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 40-50 Feet Below Ground Surface



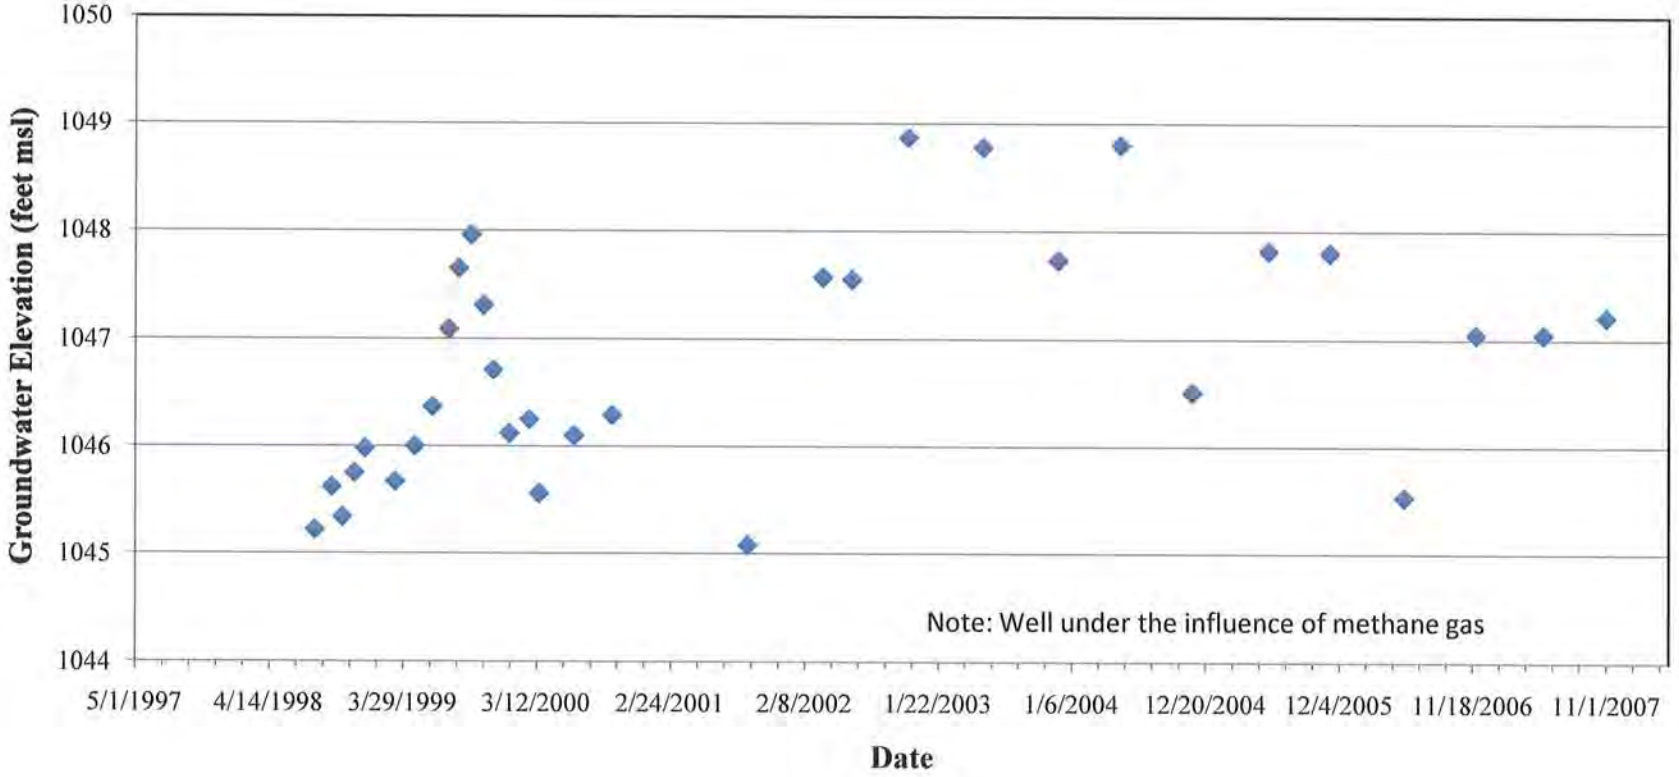
Groundwater Elevations in Well GM-42
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 72-82 Feet Below Ground Surface



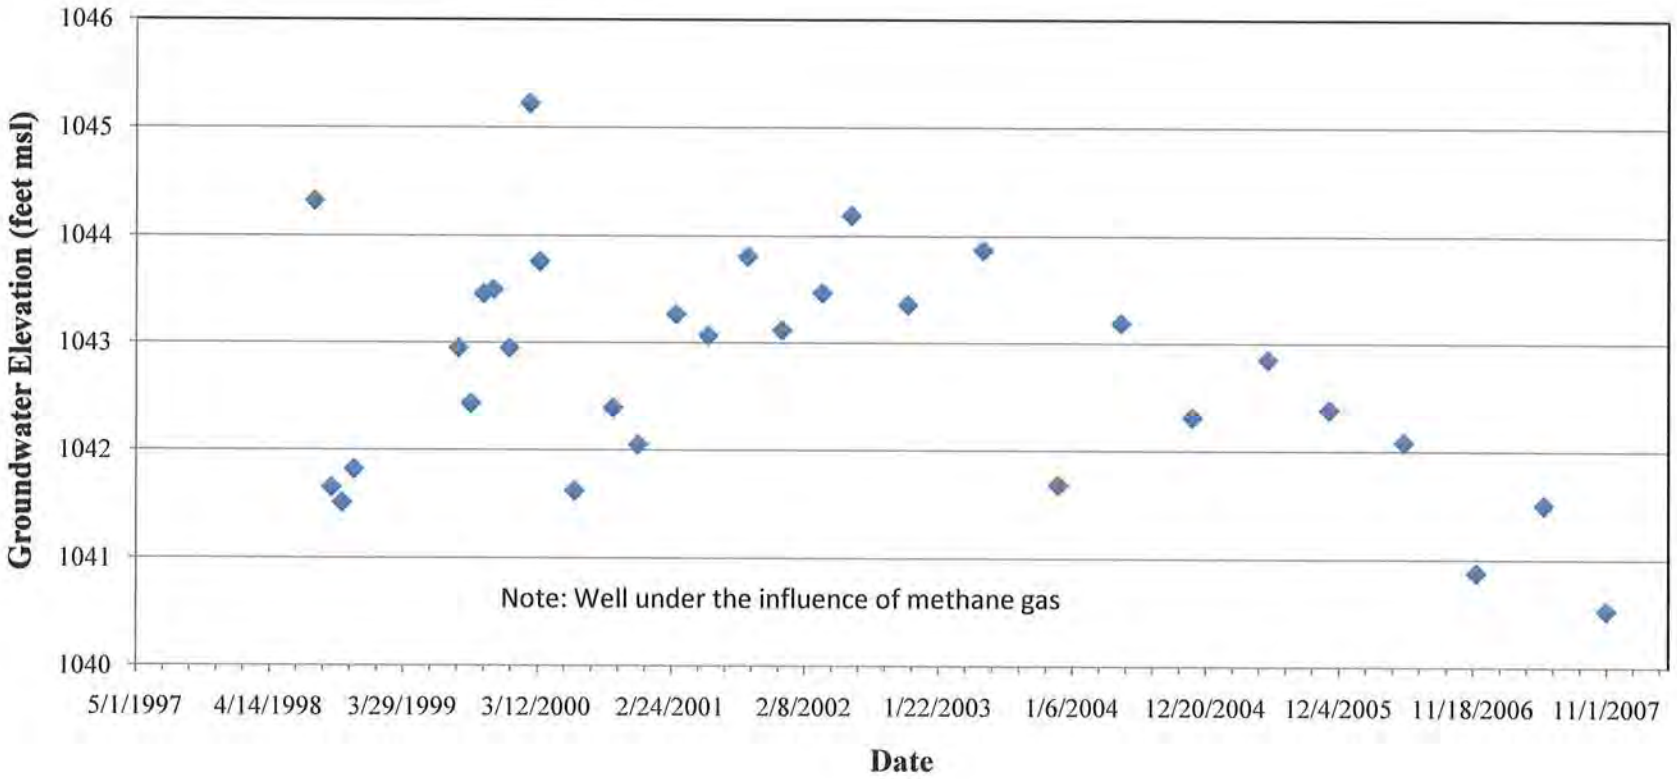
Groundwater Elevations in Well GM-43
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 64-74 Feet Below Ground Surface



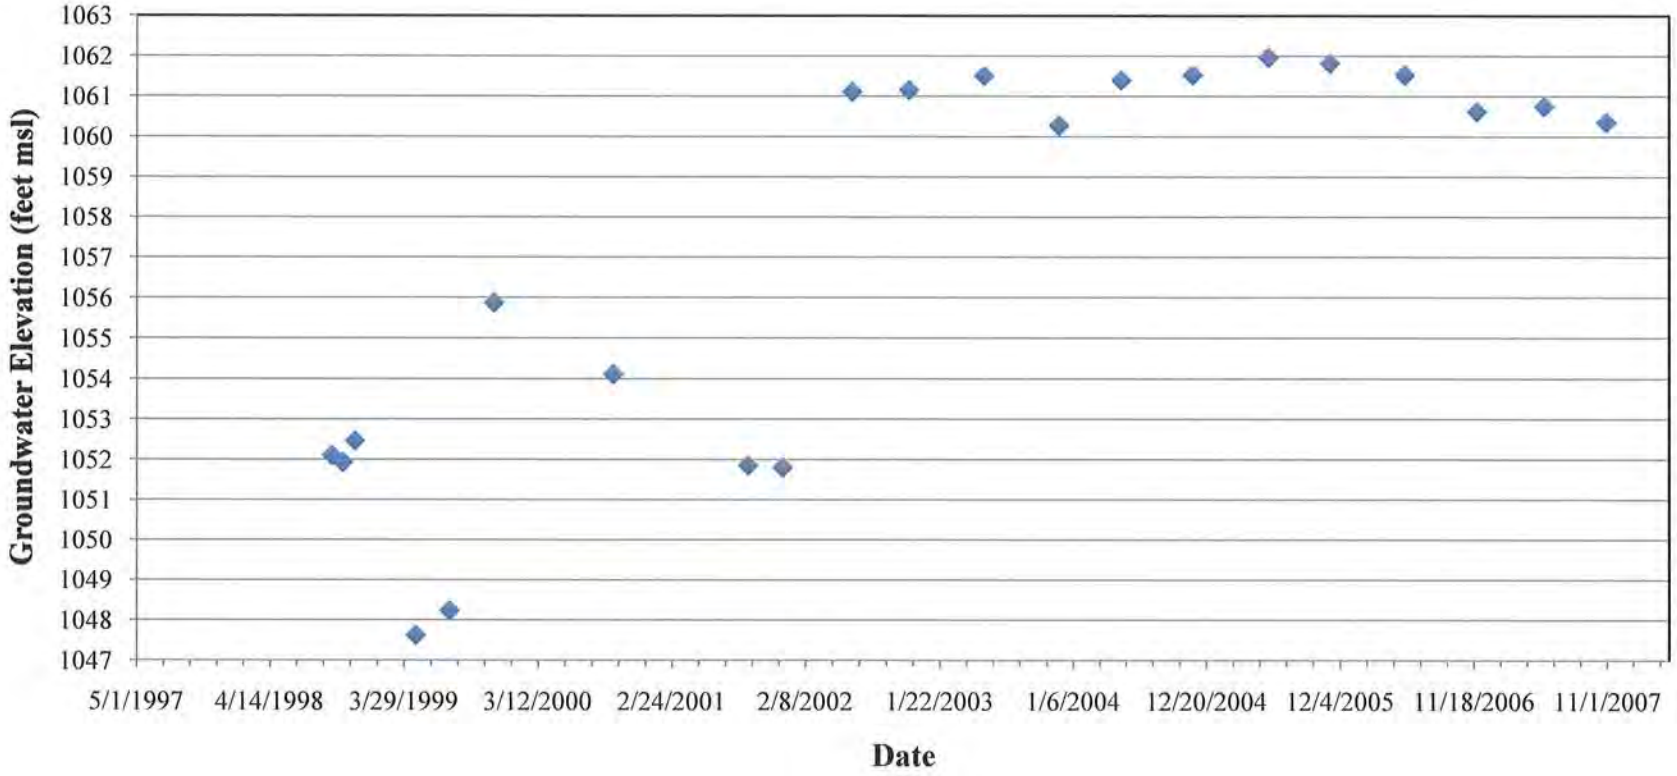
Groundwater Elevations in Well GM-44
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 60-80 Feet Below Ground Surface



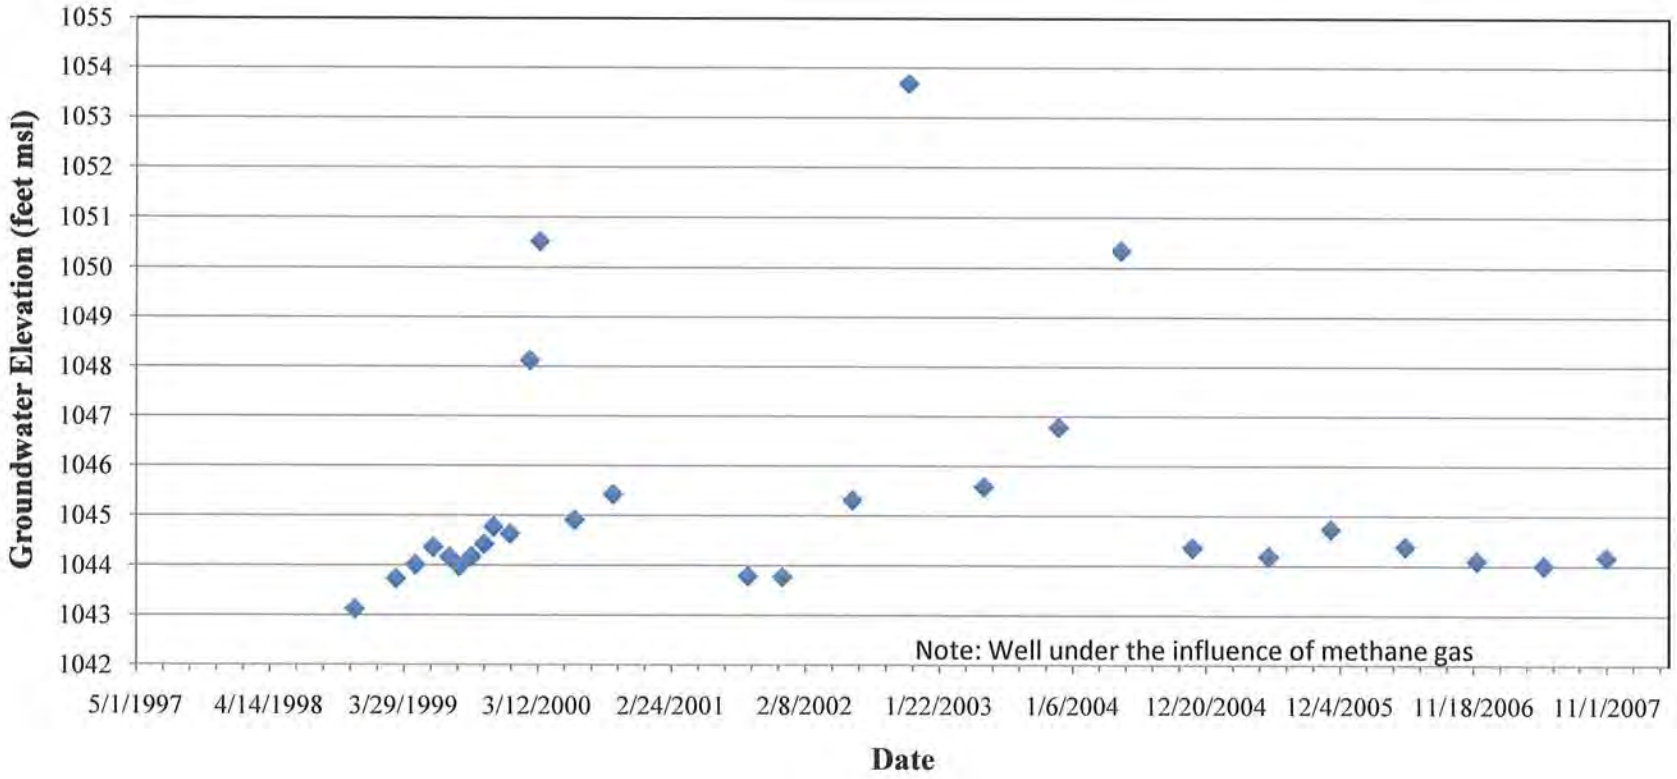
Groundwater Elevations in Well GM-45
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 70-85 Feet Below Ground Surface



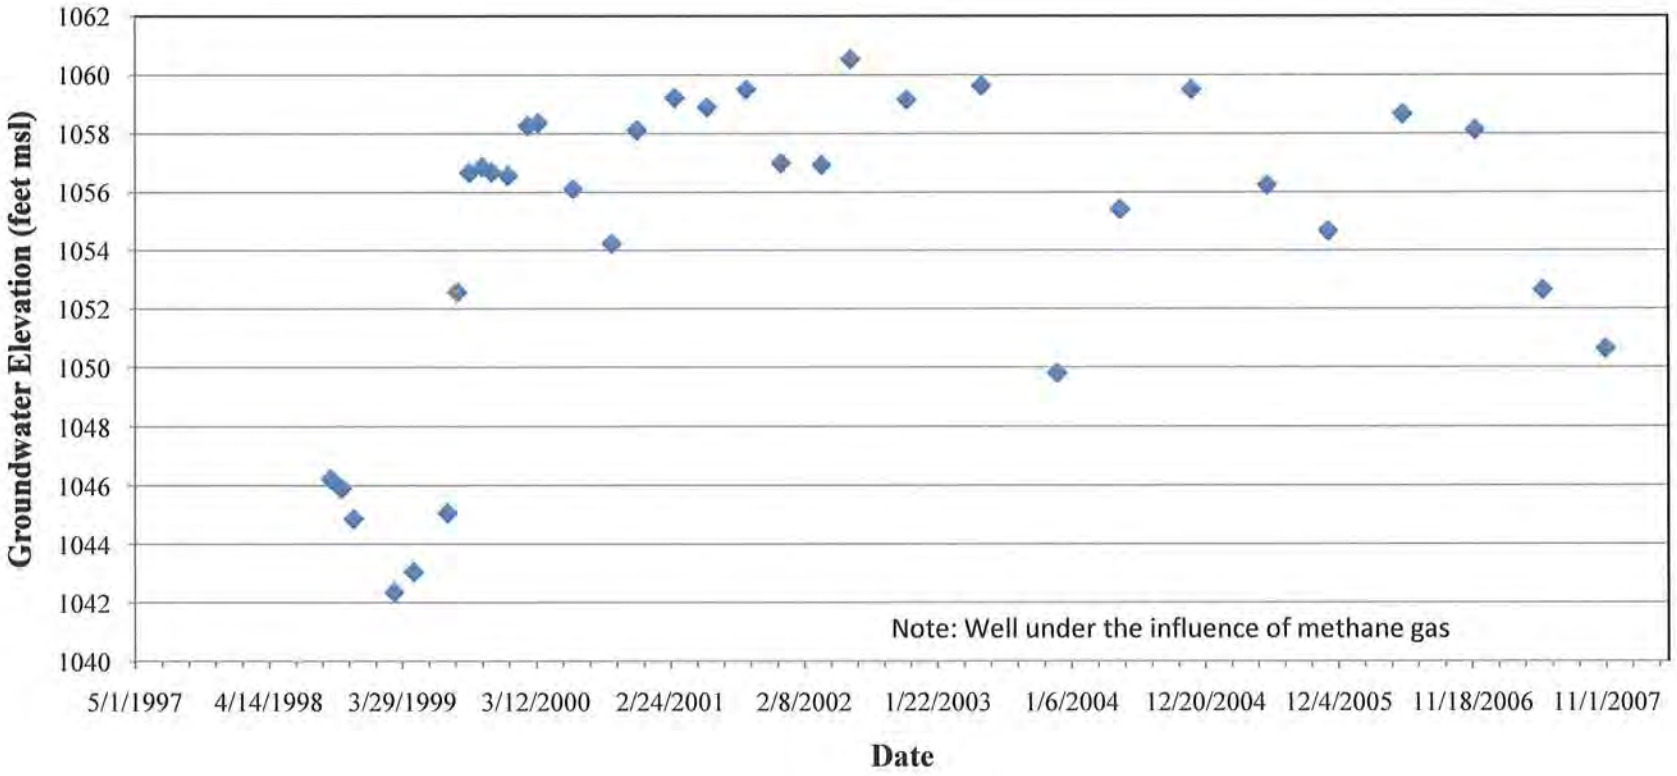
Groundwater Elevations in Well GM-46
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 65-75 Feet Below Ground Surface



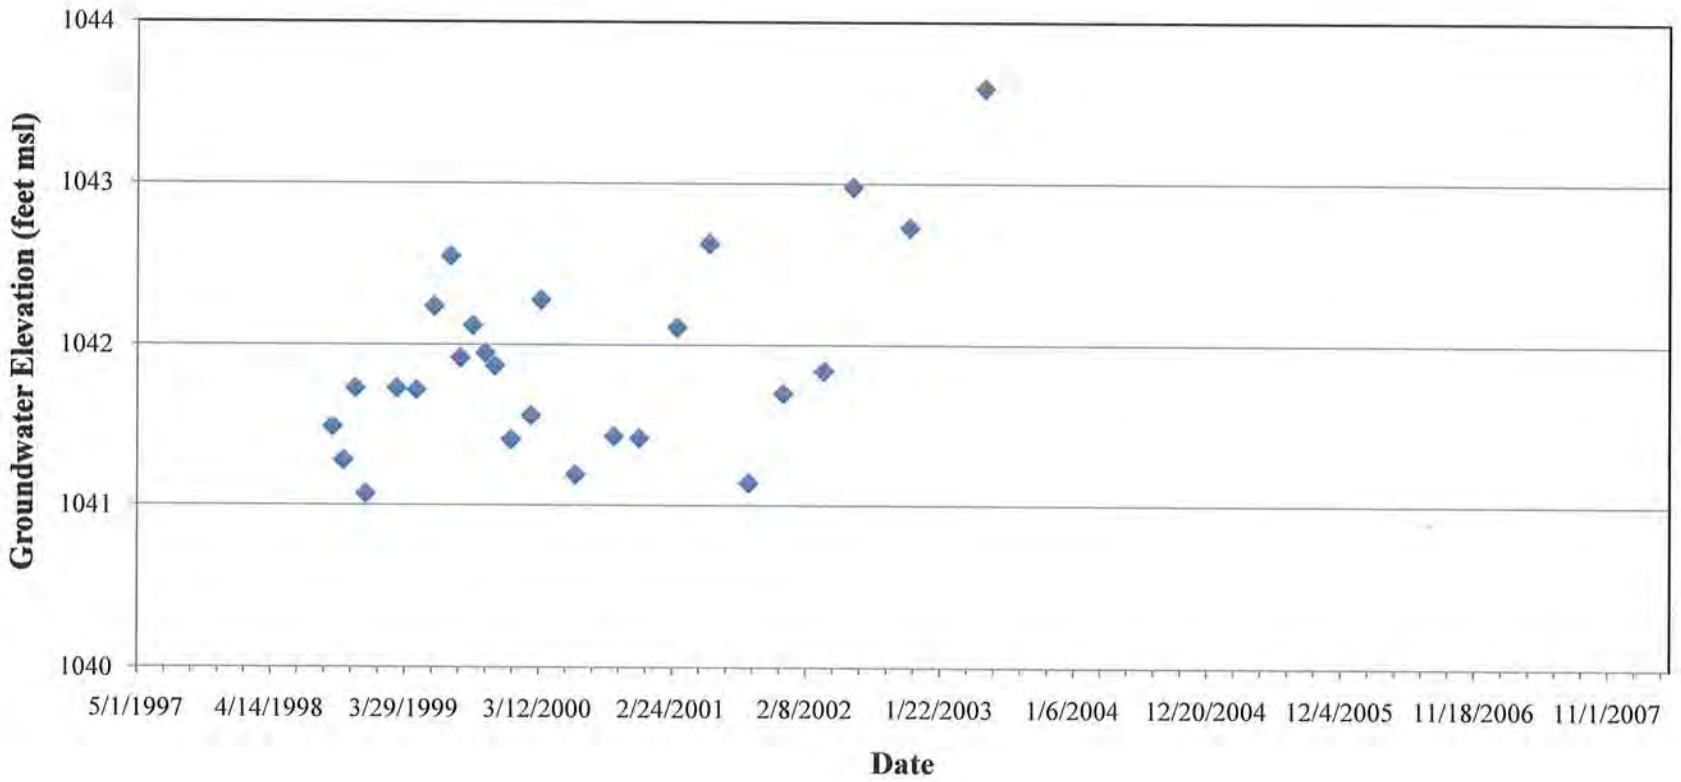
Groundwater Elevations in Well GM-47
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 69-84 Feet Below Ground Surface



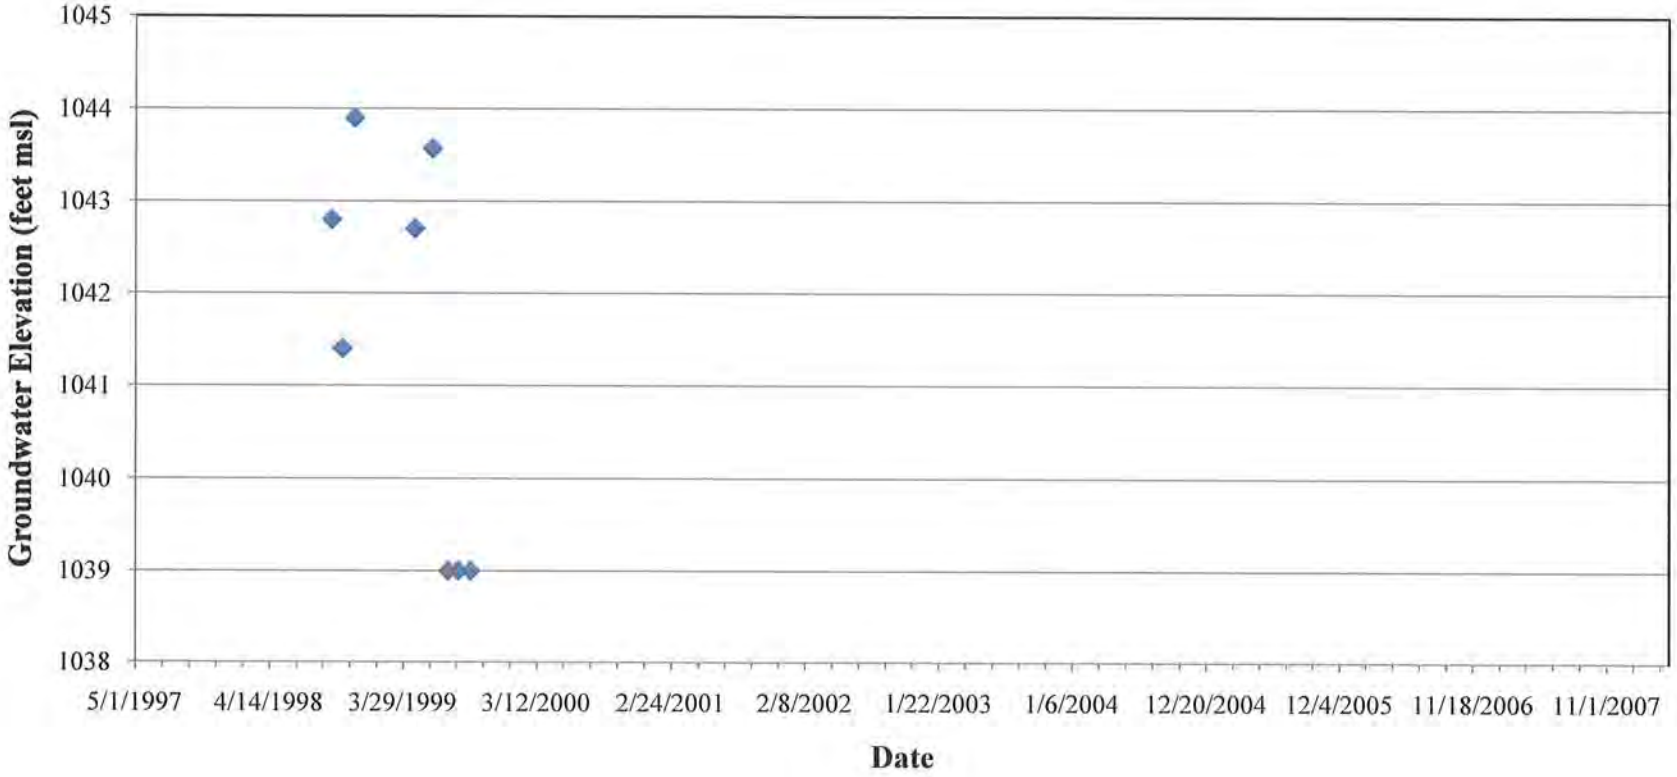
Groundwater Elevations in Well GM-48
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 65-85 Feet Below Ground Surface



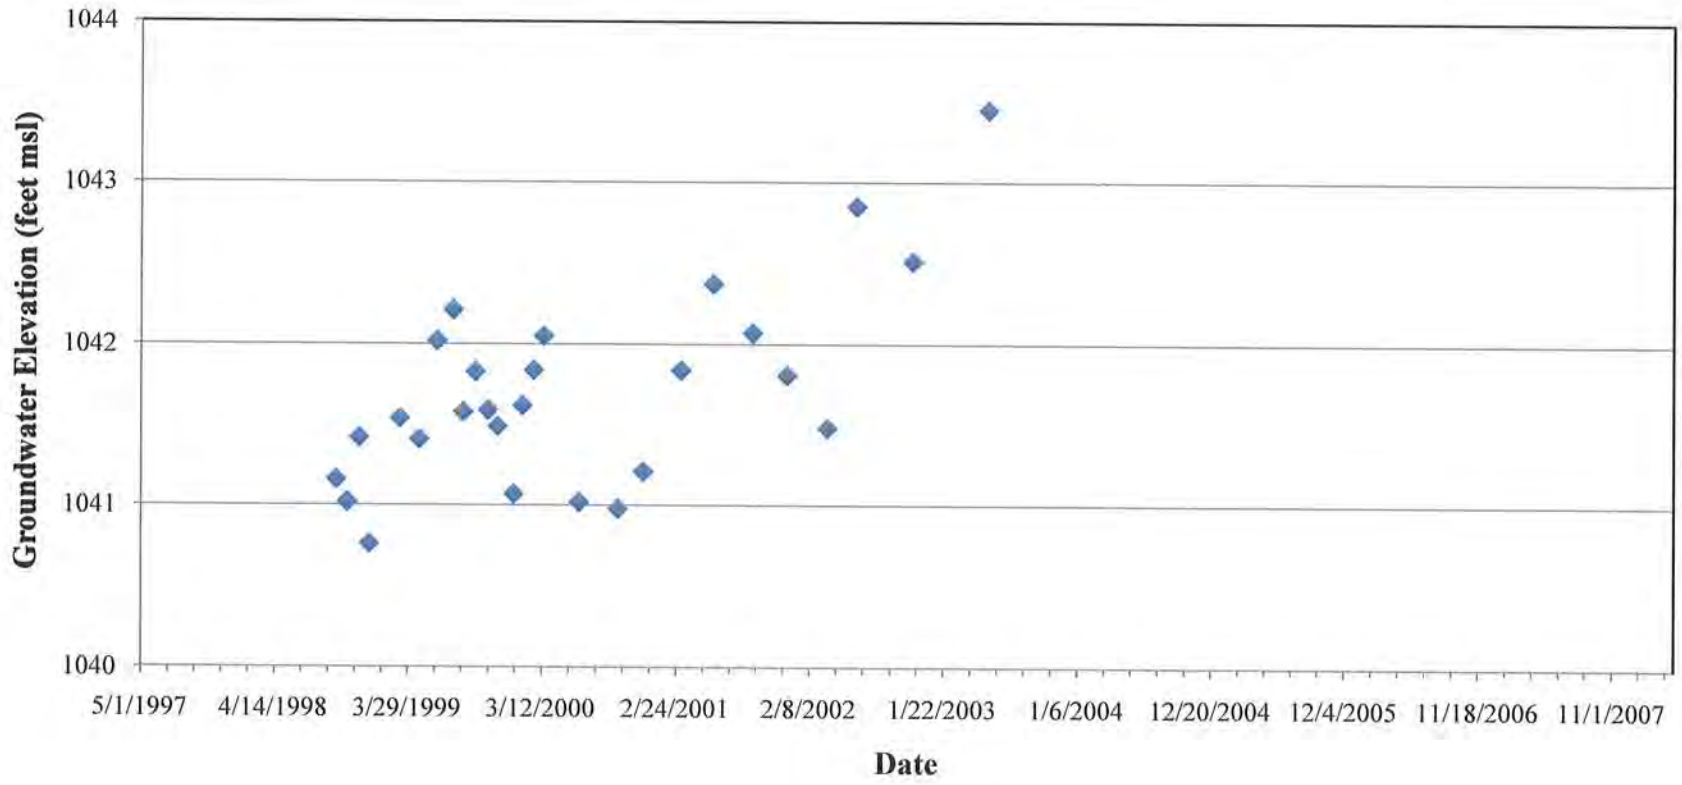
Groundwater Elevations in Well GM-49
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 83.5-93.5 Feet Below Ground Surface



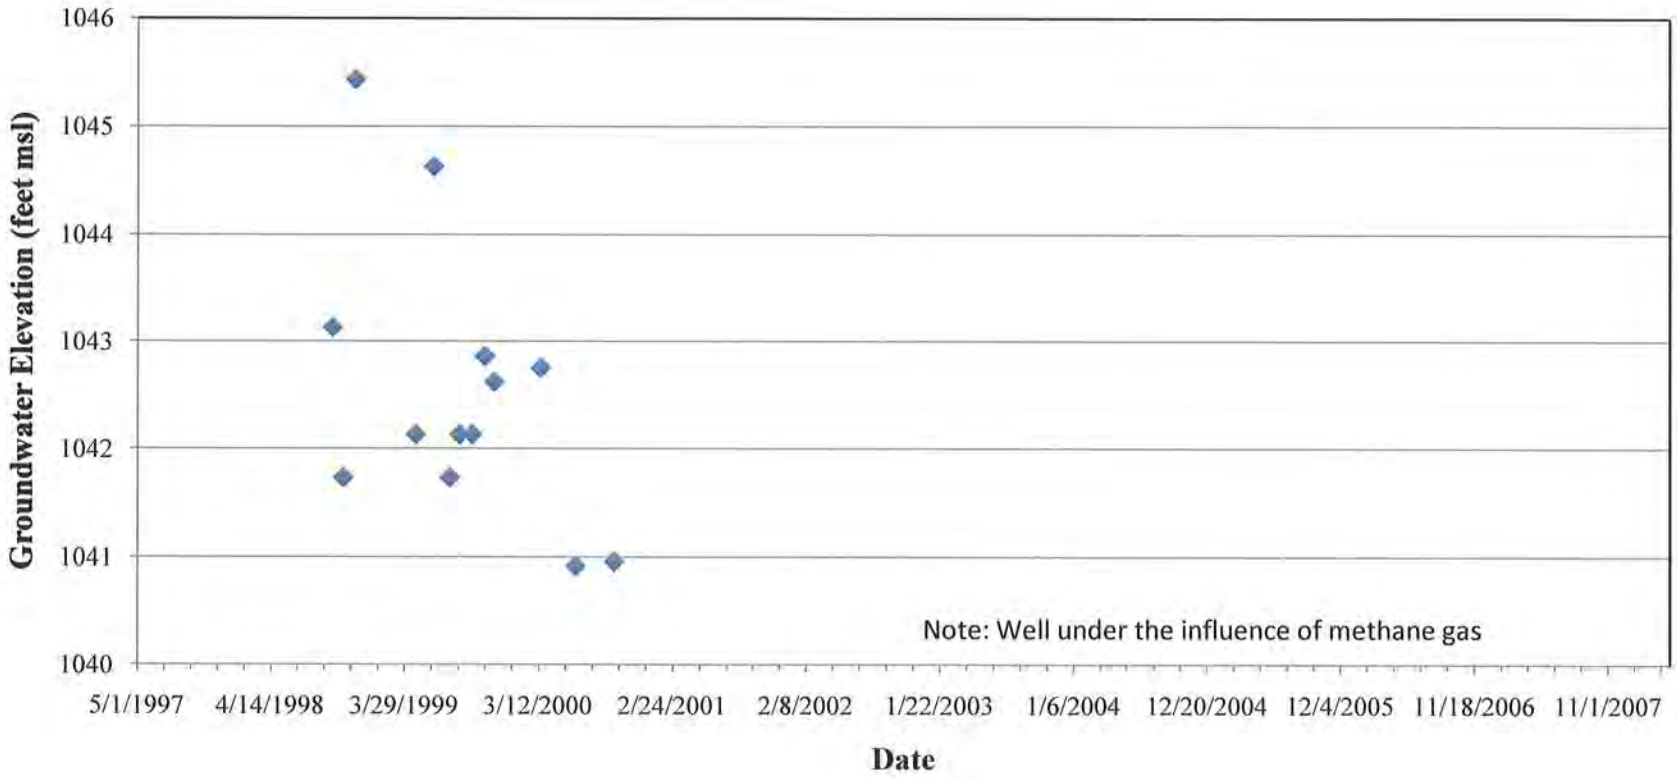
Groundwater Elevations in Well GM-50
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 80.5-95.5 Feet Below Ground Surface



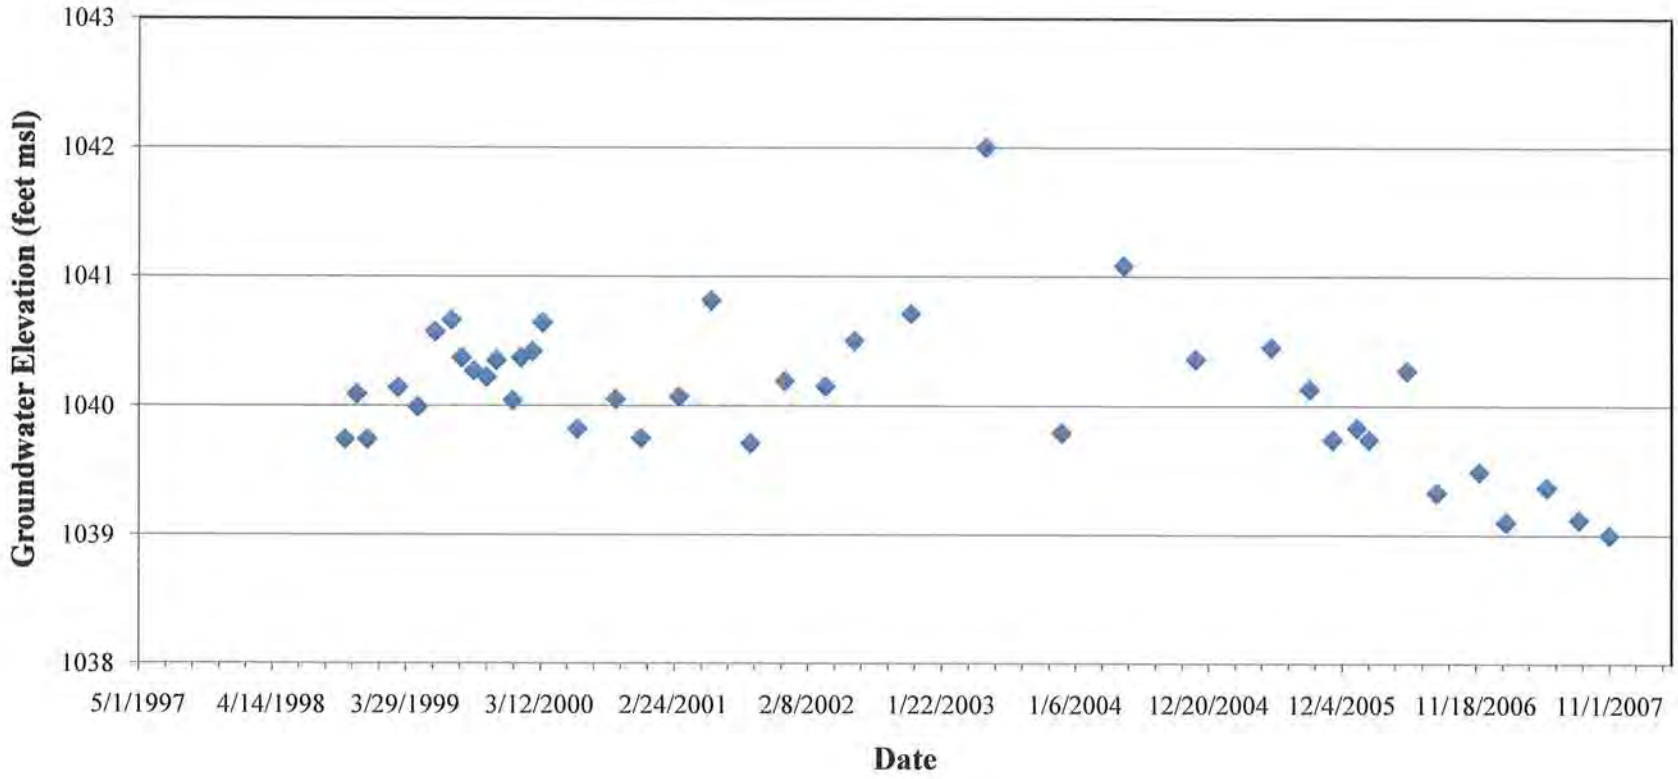
Groundwater Elevations in Well GM-51
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 67-77 Feet Below Ground Surface



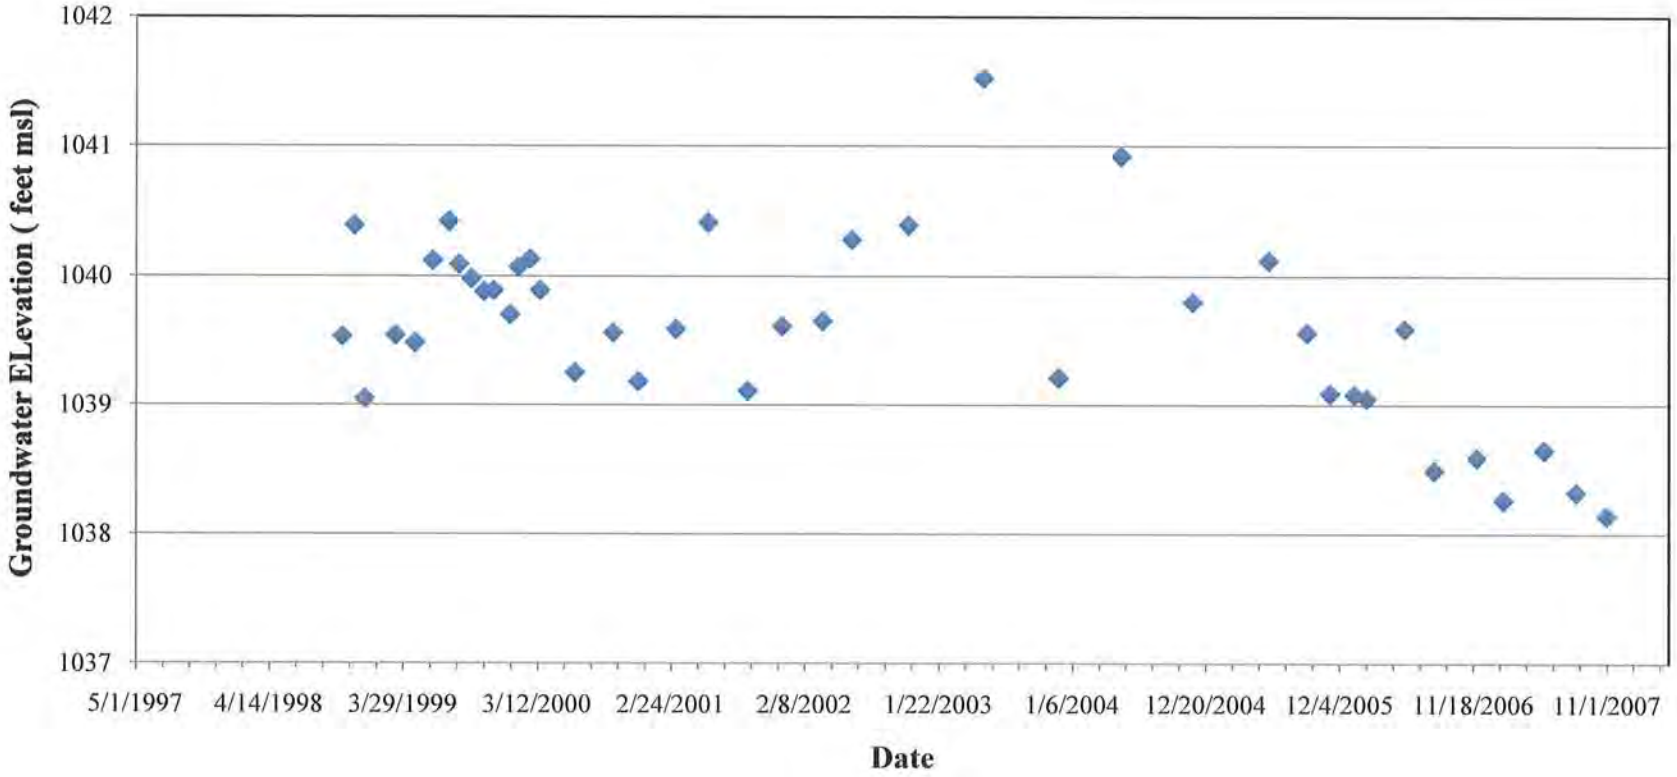
Groundwater Elevations in Well GM-52
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 75-95 Feet Below Ground Surface



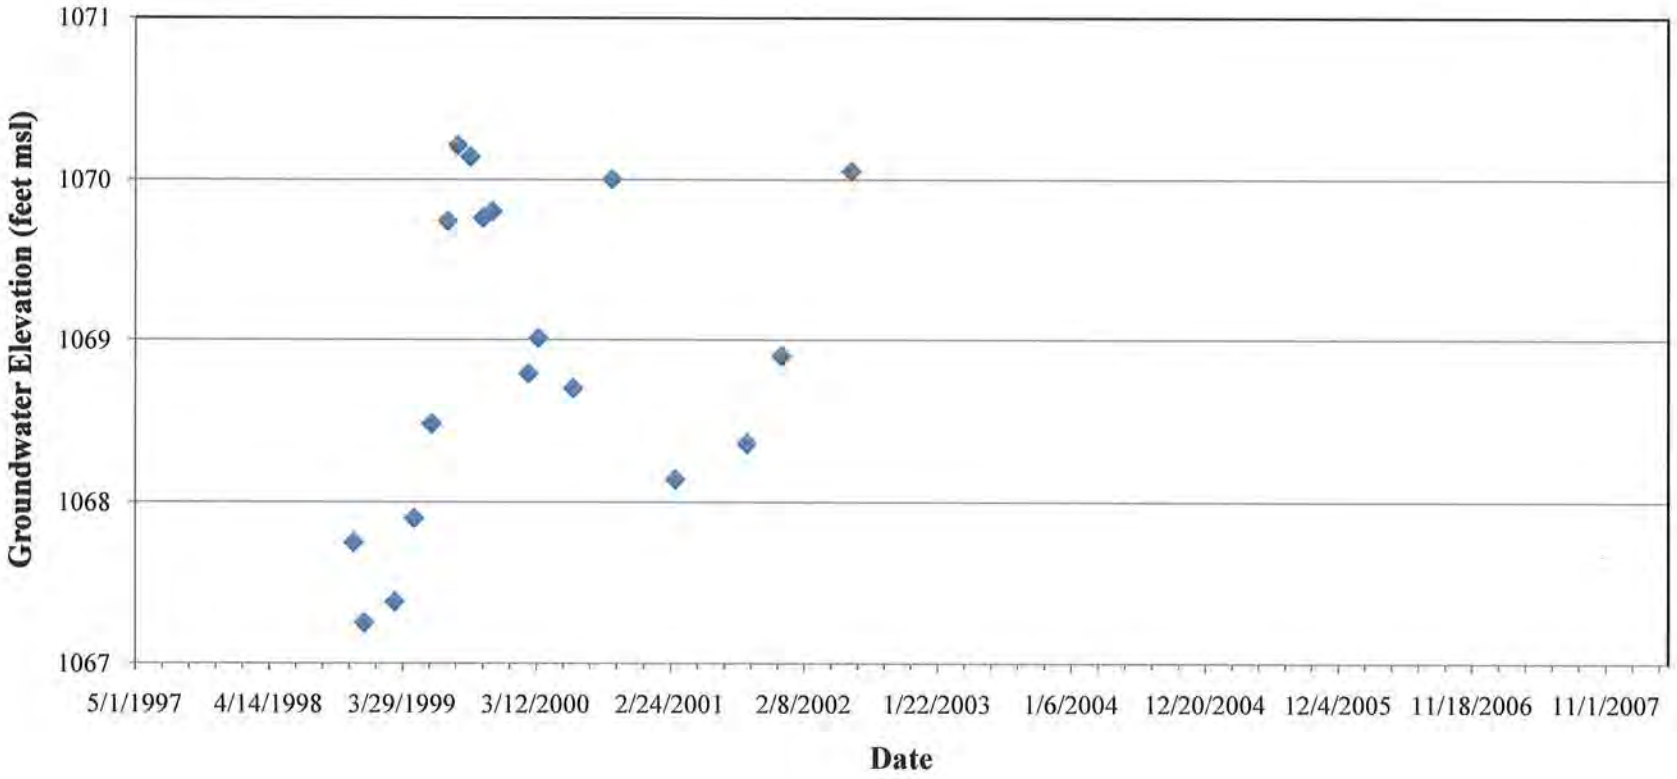
Groundwater Elevations in Well GM-53B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 195-205 Feet Below Ground Surface



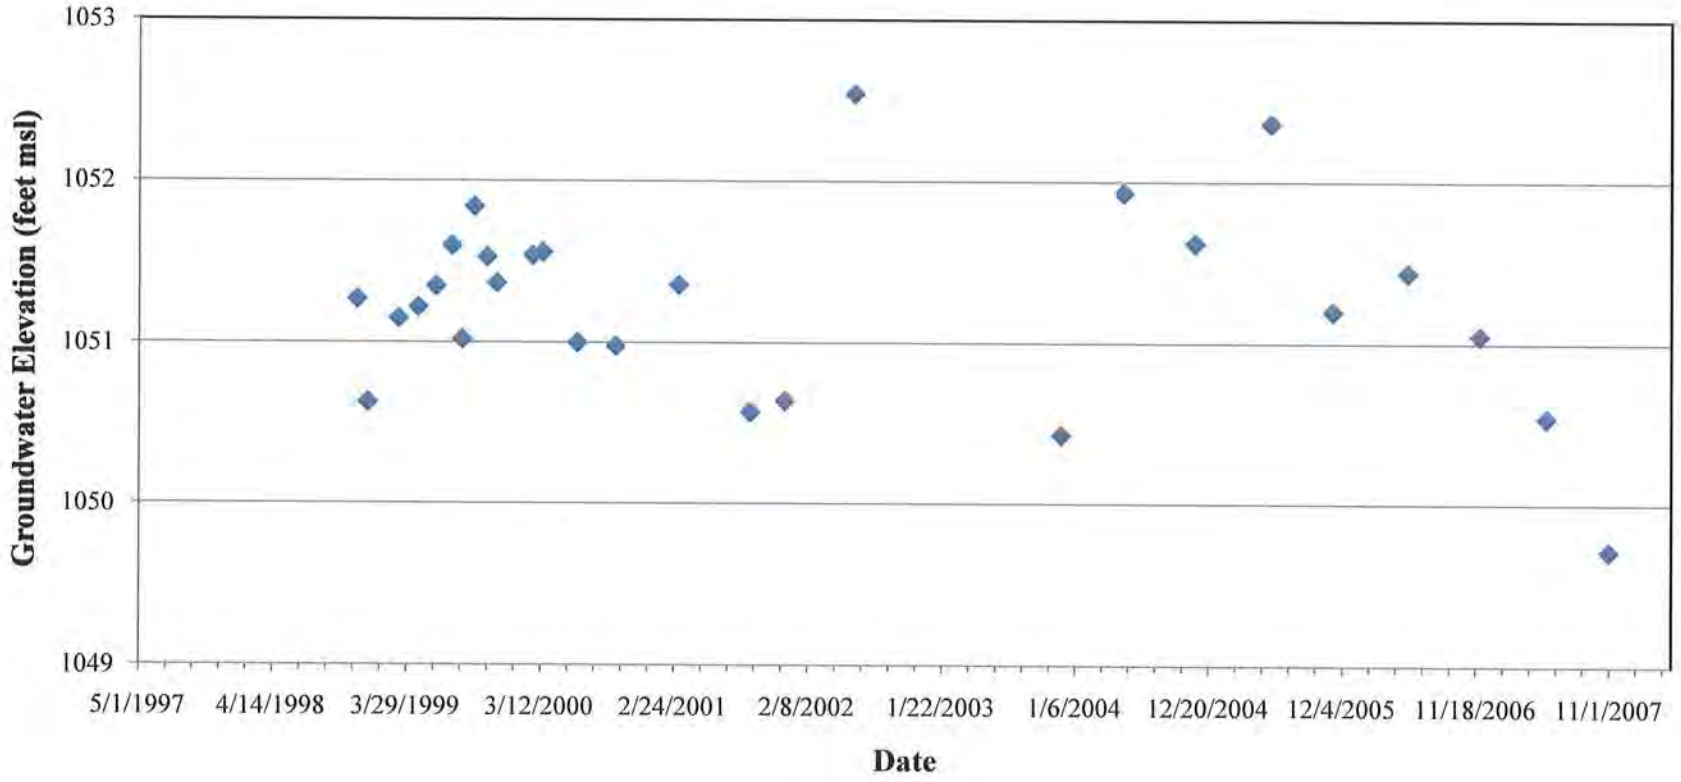
Groundwater Elevations in Well GM-53A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 79-89 Feet Below Ground Surface



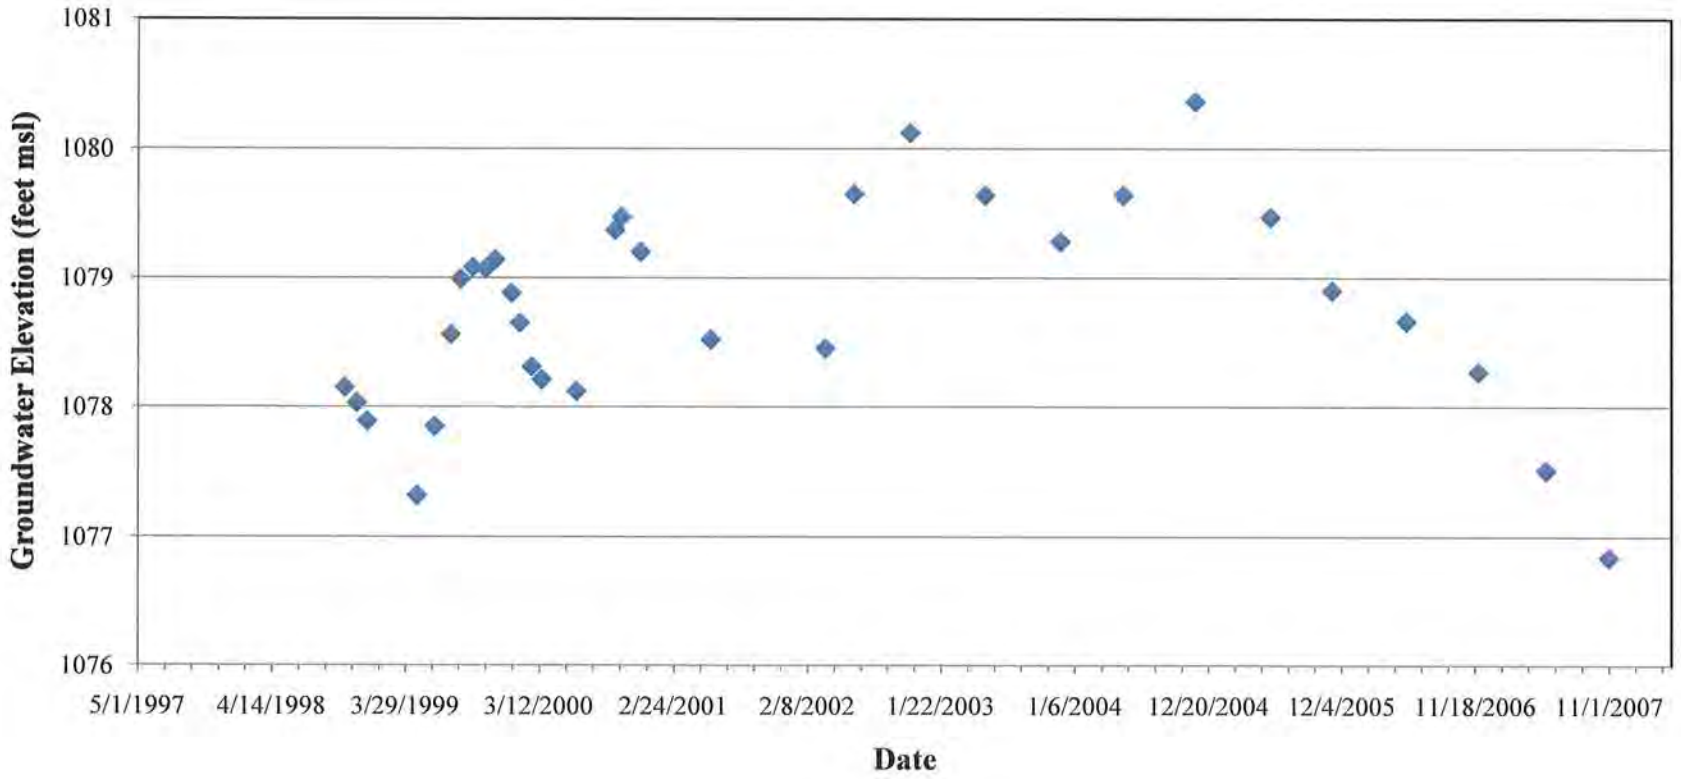
Groundwater Elevations in Well GM-54
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 80-90 Feet Below Ground Surface



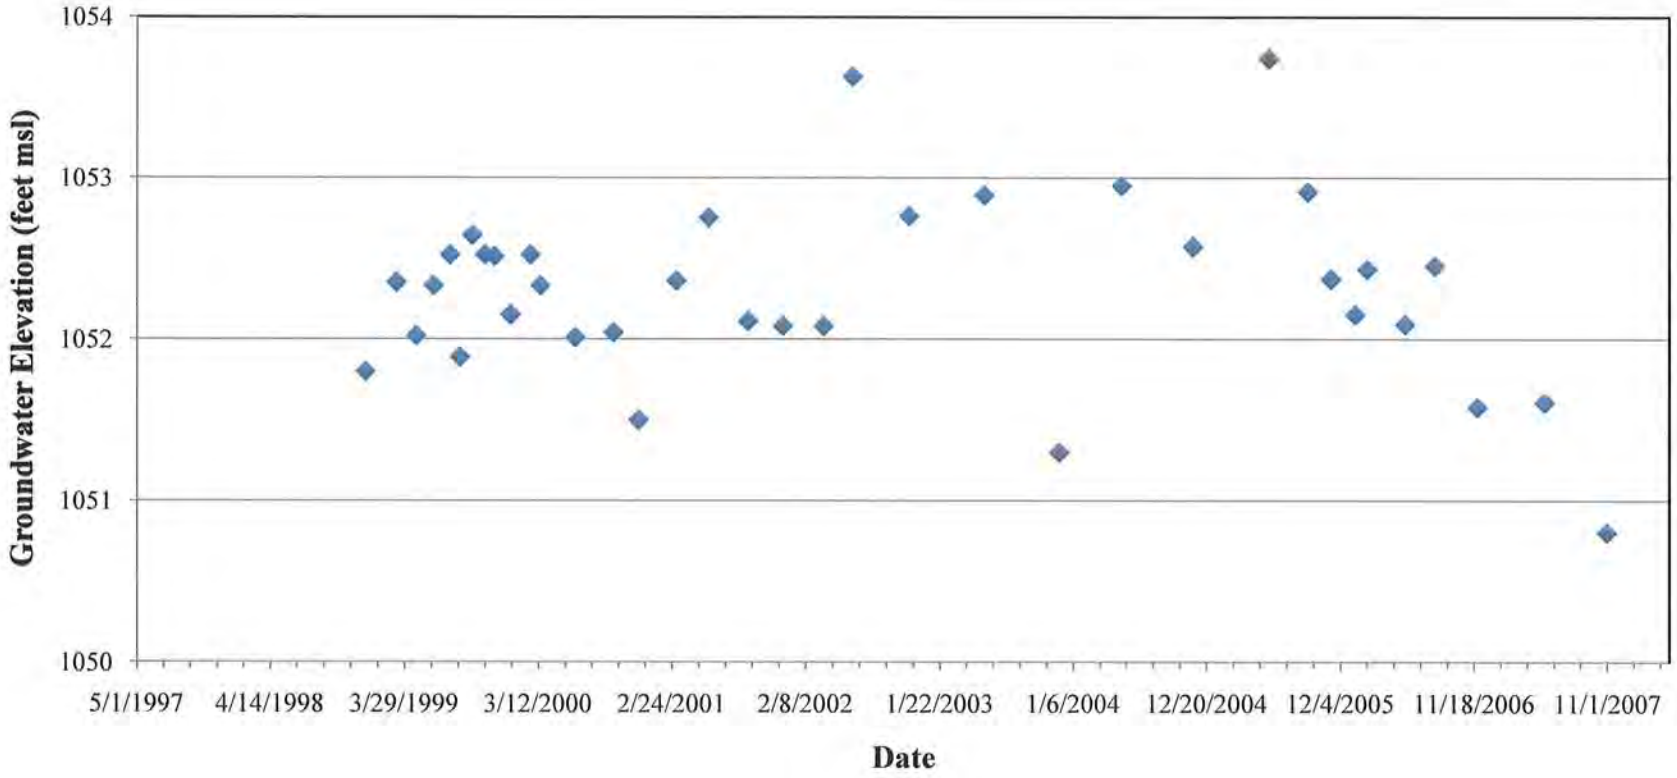
Groundwater Elevations in Well GM-55
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 75-85 Feet Below Ground Surface



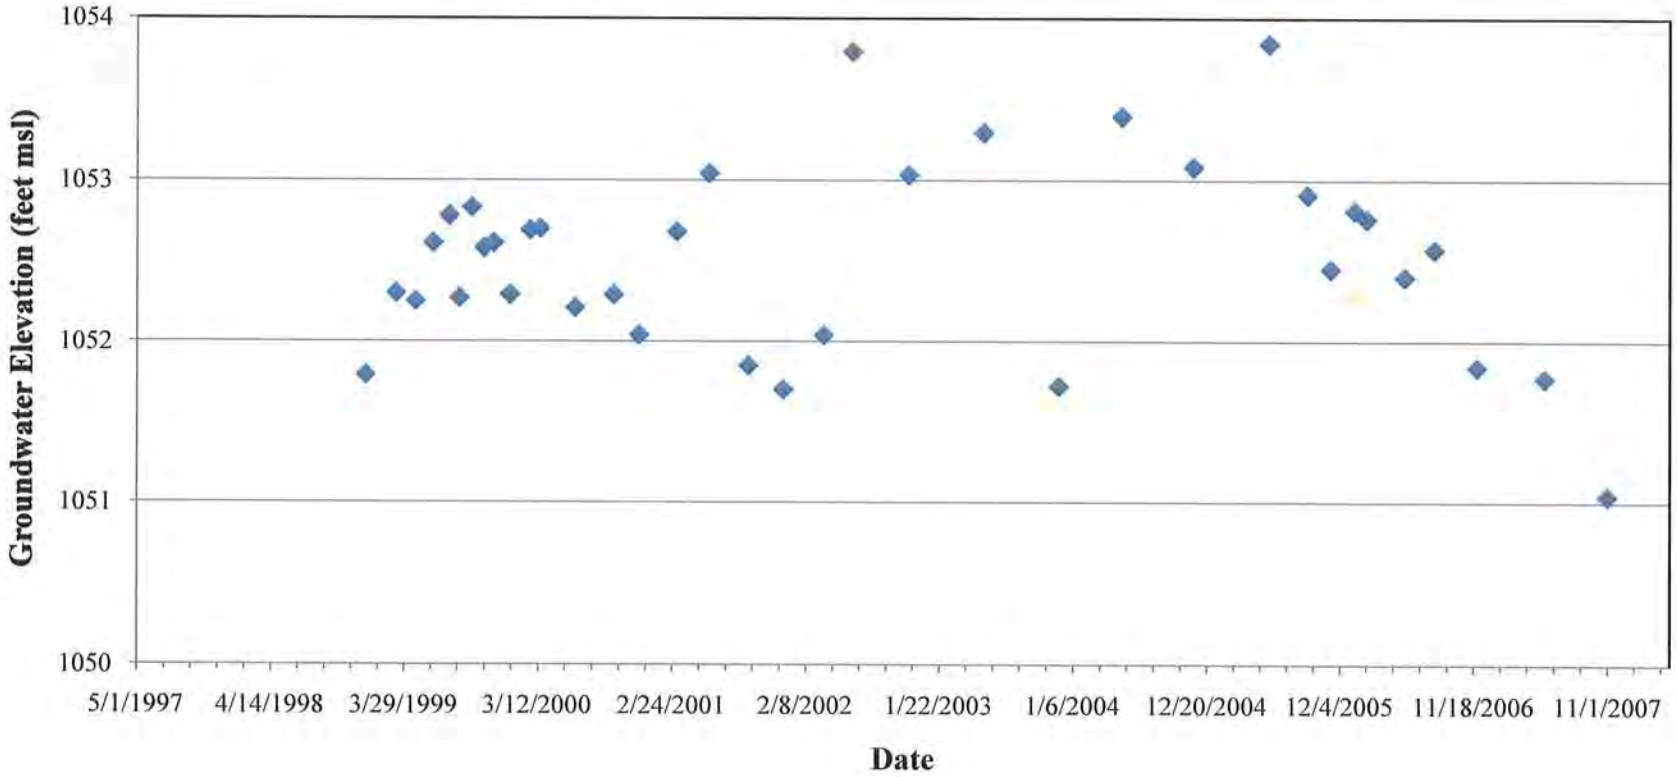
Groundwater Elevations in Well GM-5
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 32-47 Feet Below Ground Surface



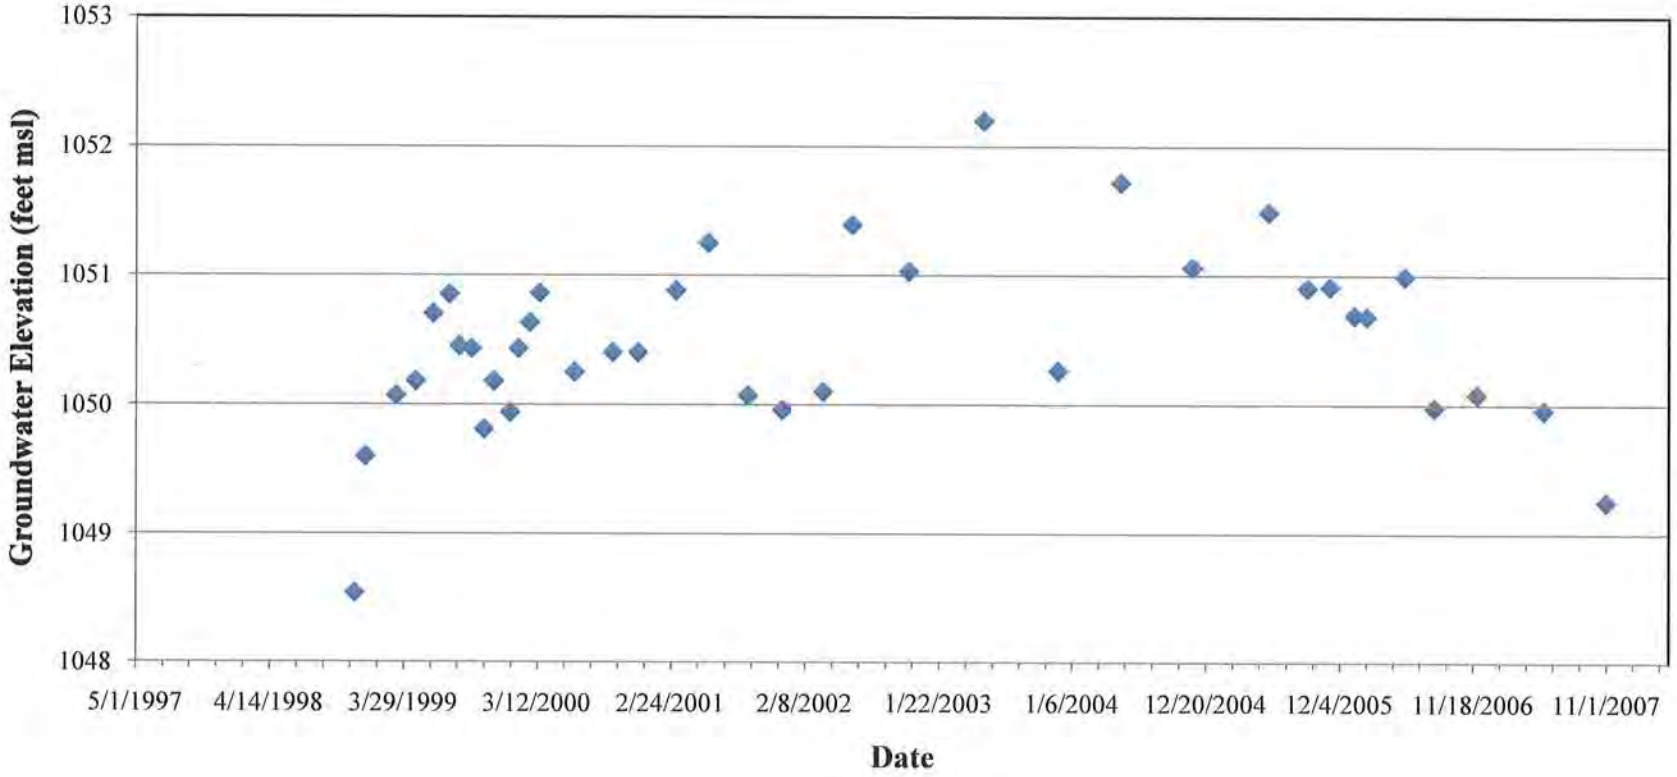
Groundwater Elevations in Well GM-57
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 76-86 Feet Below Ground Surface



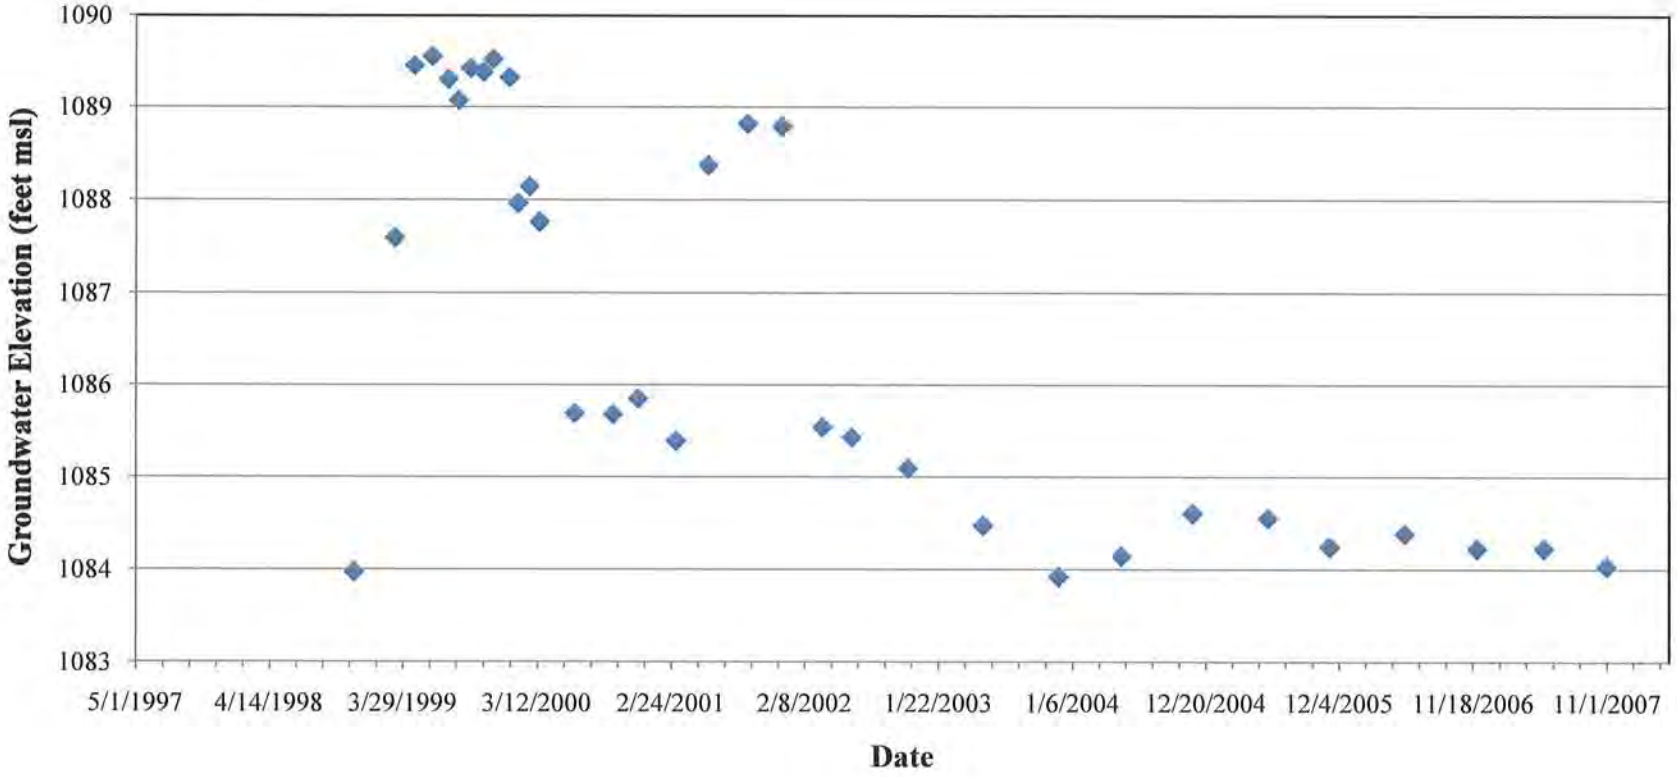
Groundwater Elevations in Well GM-58
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 75-85 Feet Below Ground Surface



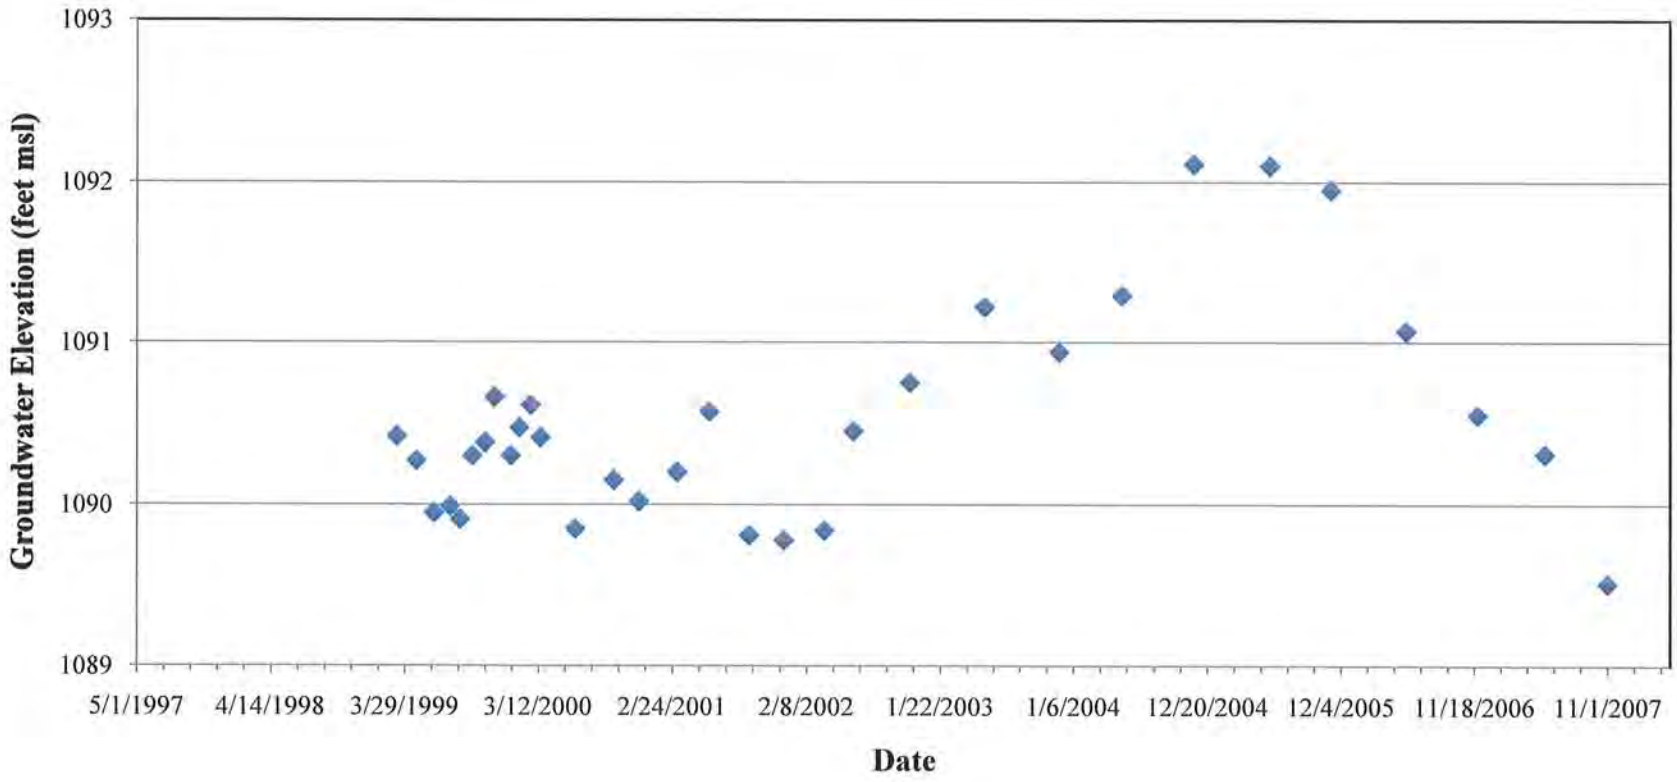
Groundwater Elevations in Well GM-59
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 114-124 Feet Below Ground Surface



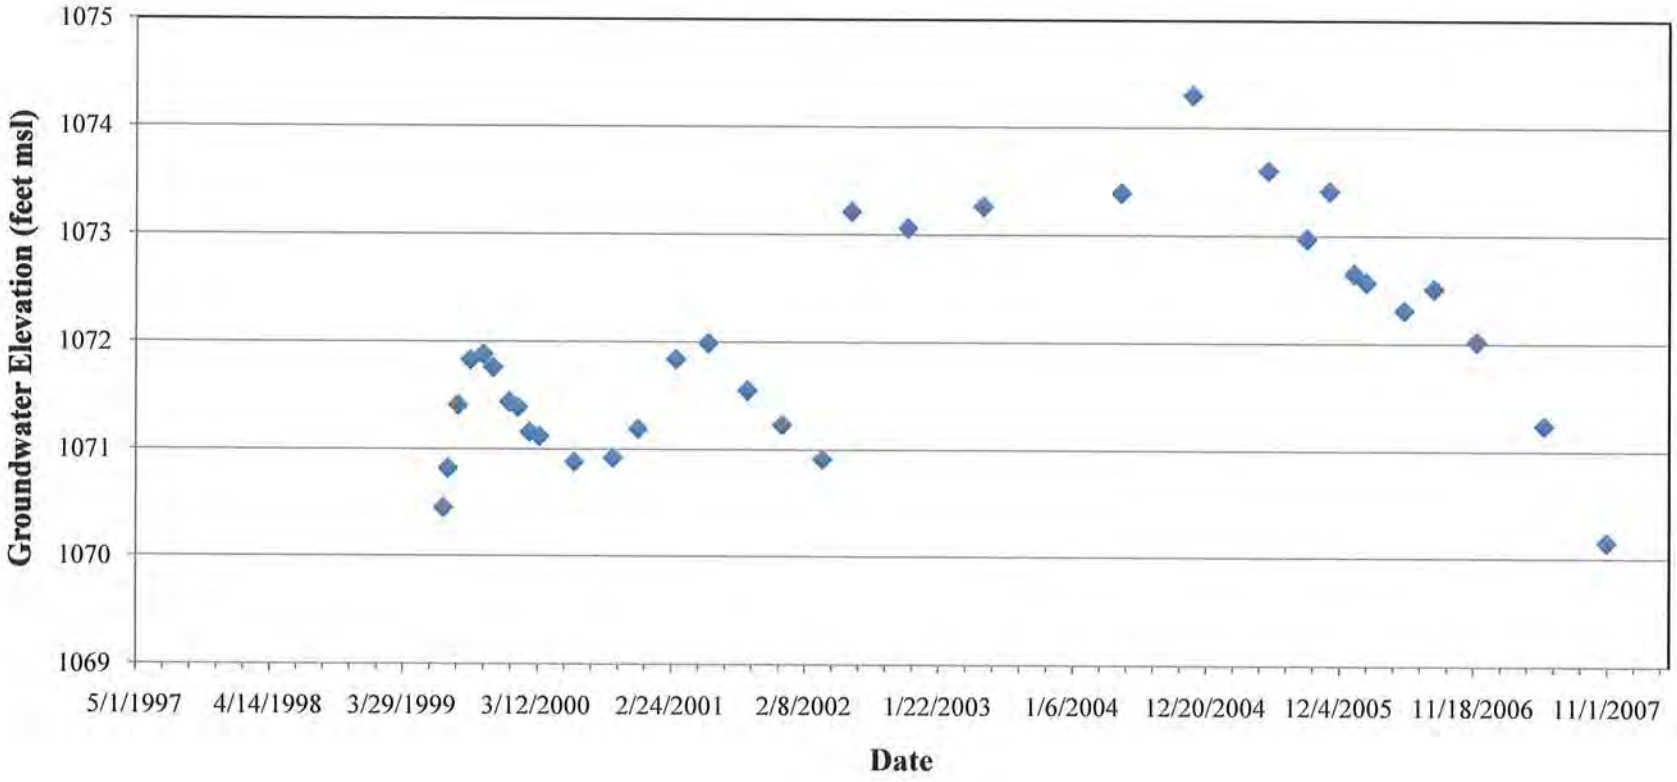
Groundwater Elevations in Well GM-60
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 102-107 Feet Below Ground Surface



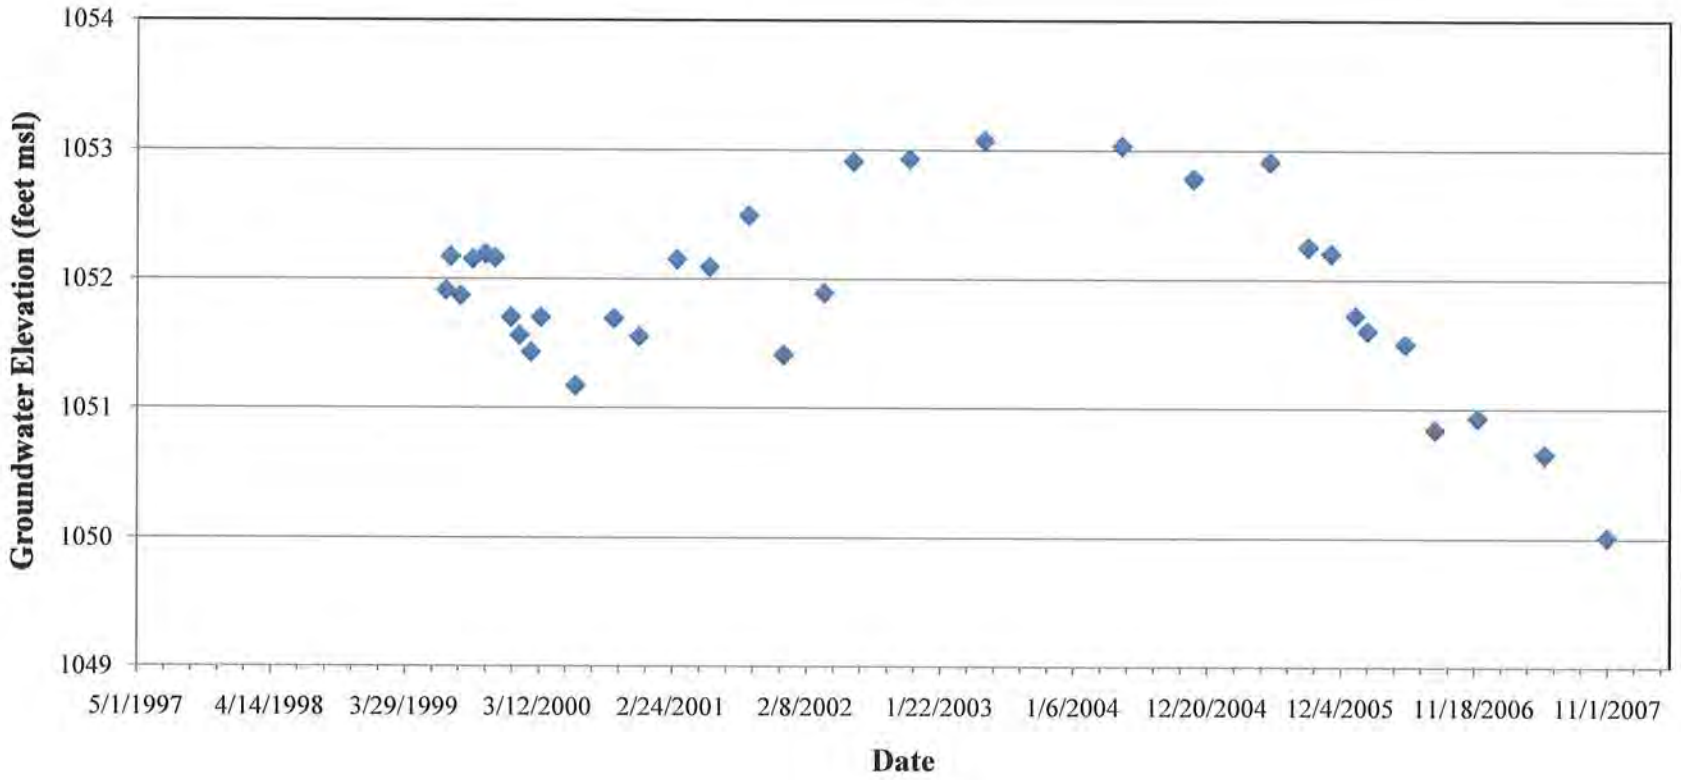
Groundwater Elevations in Well GM-61
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 138-143 Feet Below Ground Surface



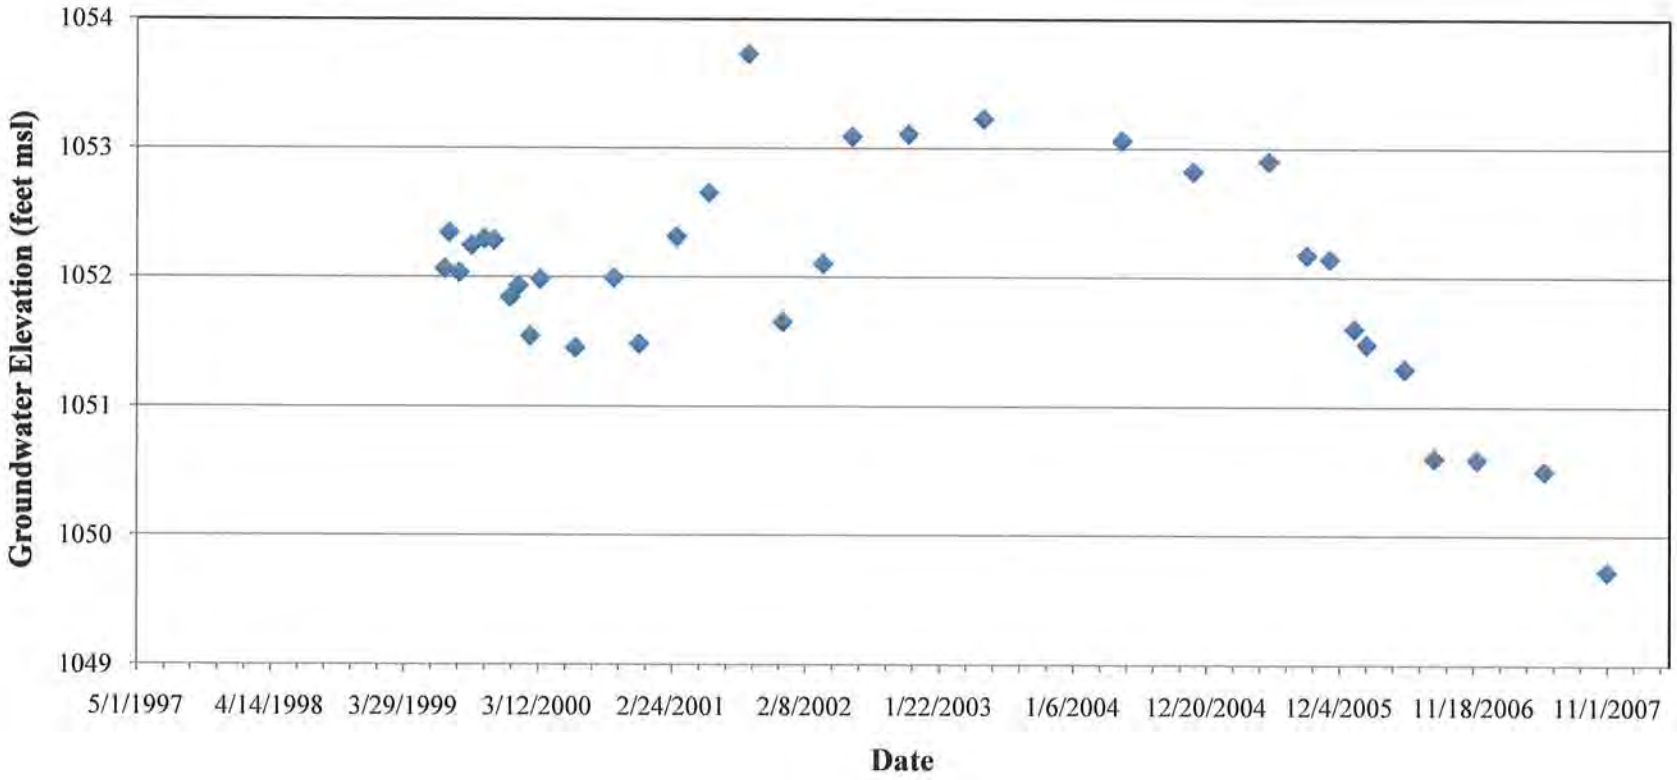
Groundwater Elevations in Well GM-62A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 90-100 Feet Below Ground Surface



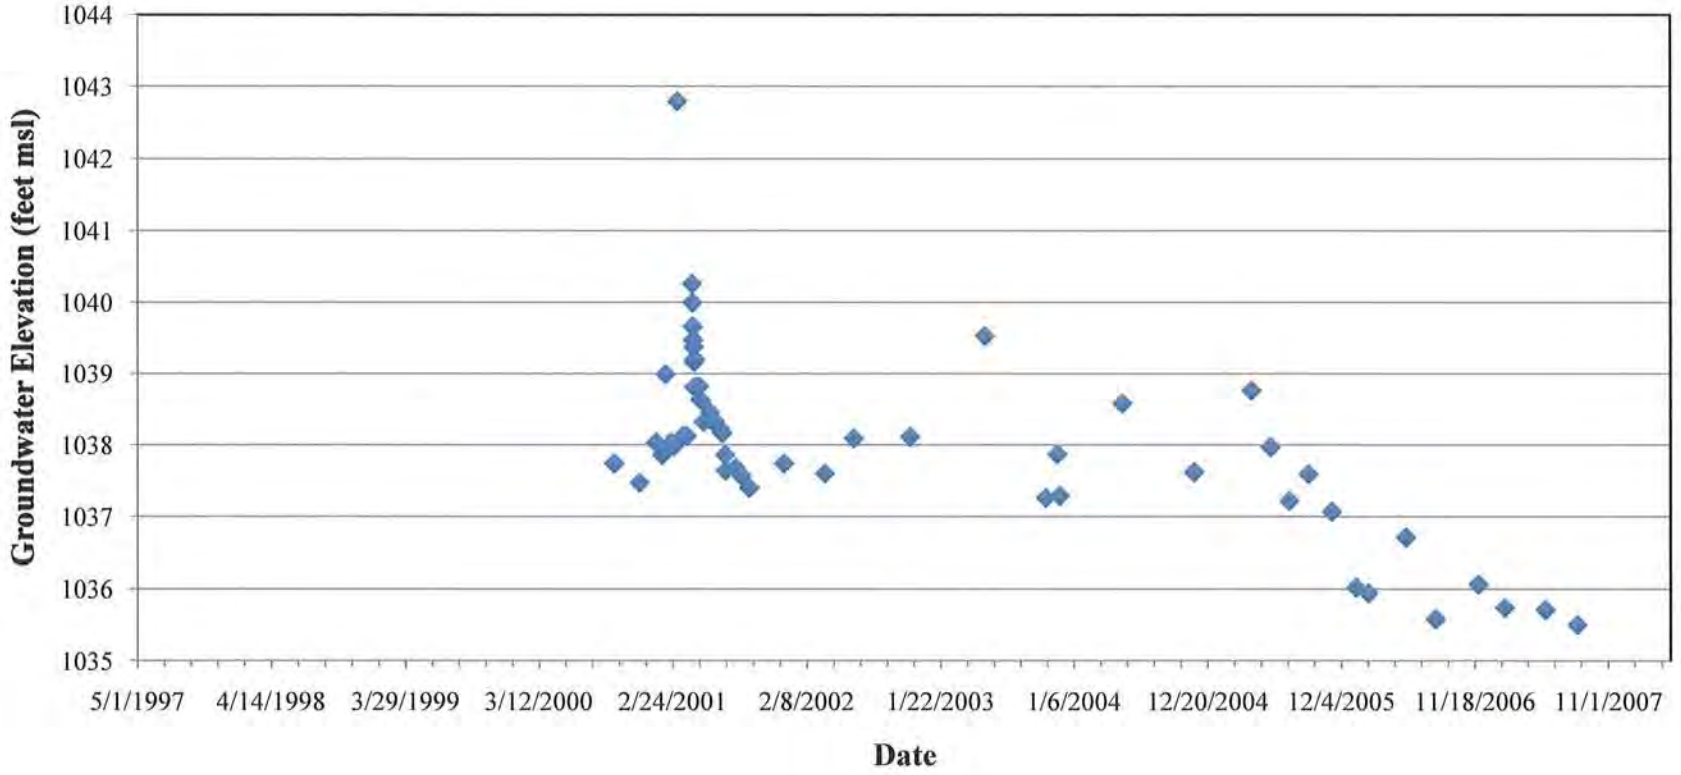
Groundwater Elevations in Well GM-62B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 195-205 Feet Below Ground Surface



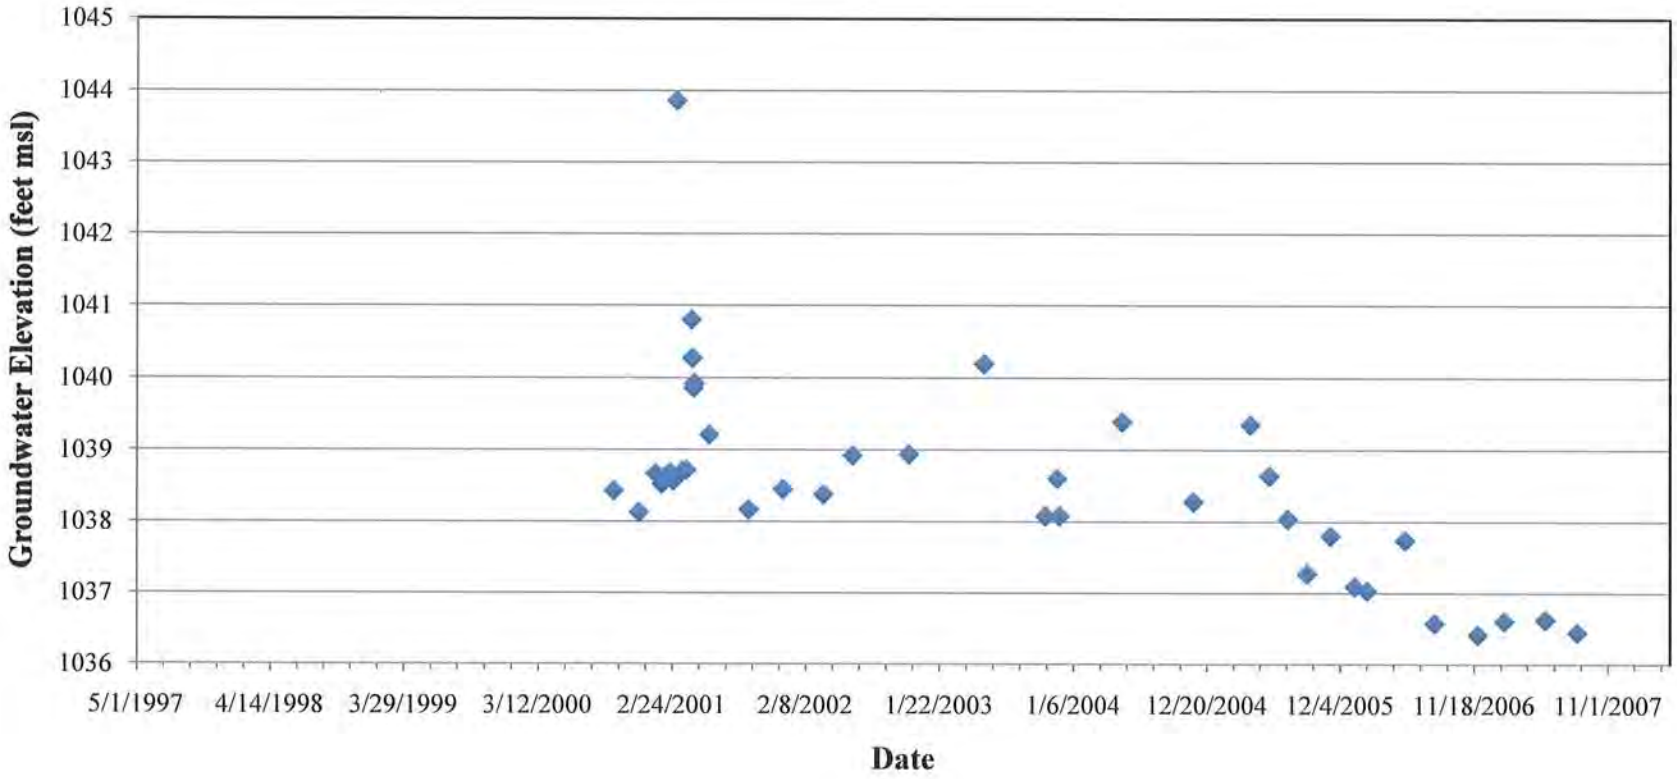
Groundwater Elevations in Well GM-62C
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 315-325 Feet Below Ground Surface



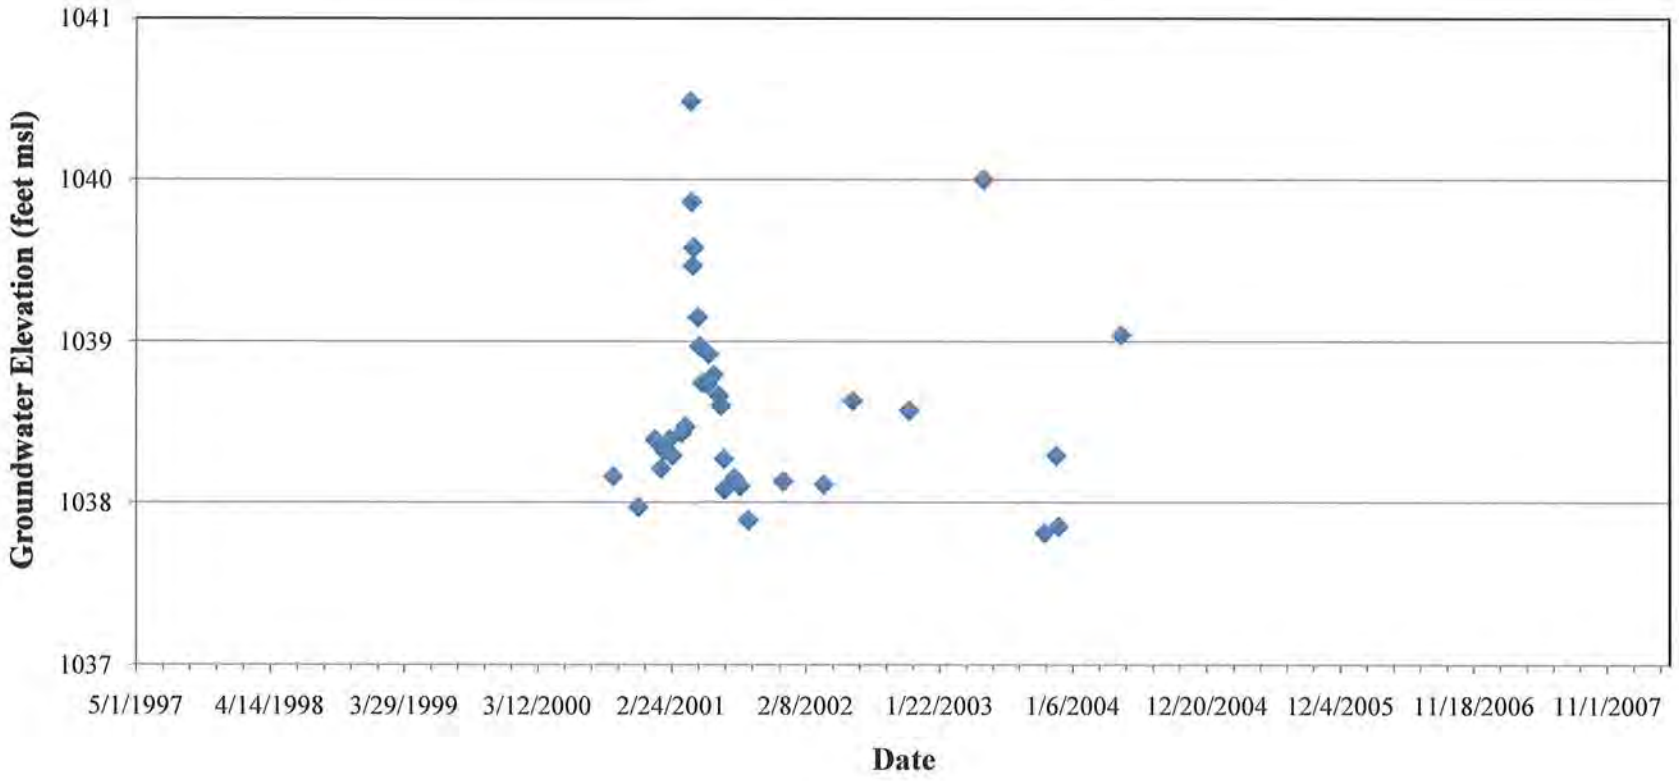
Groundwater Elevations in Well GM-63A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 45-50 Feet Below Ground Surface



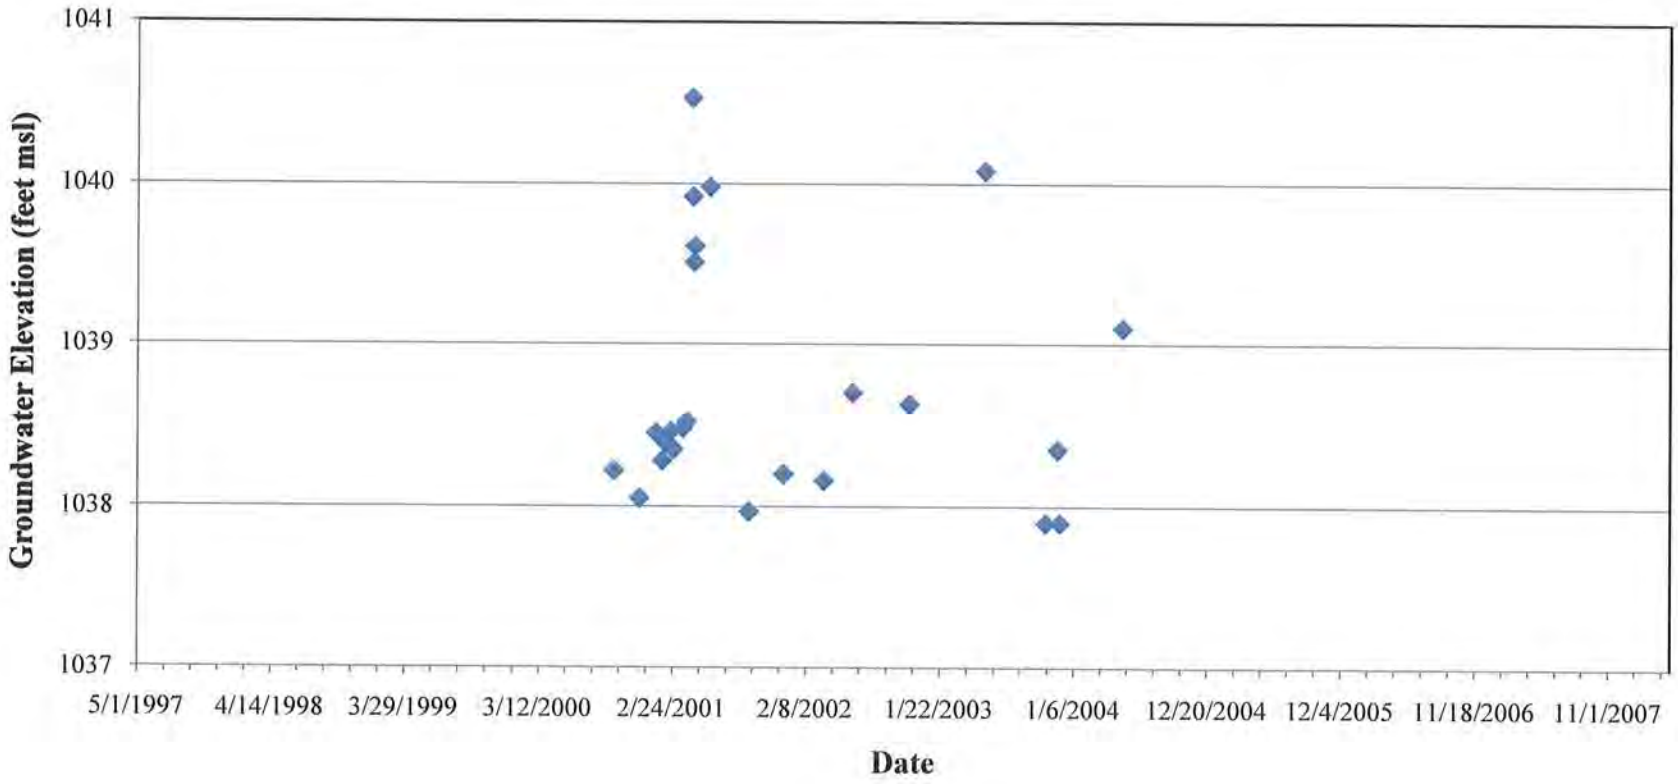
Groundwater Elevations in Well GM-63B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 105-110 Feet Below Ground Surface



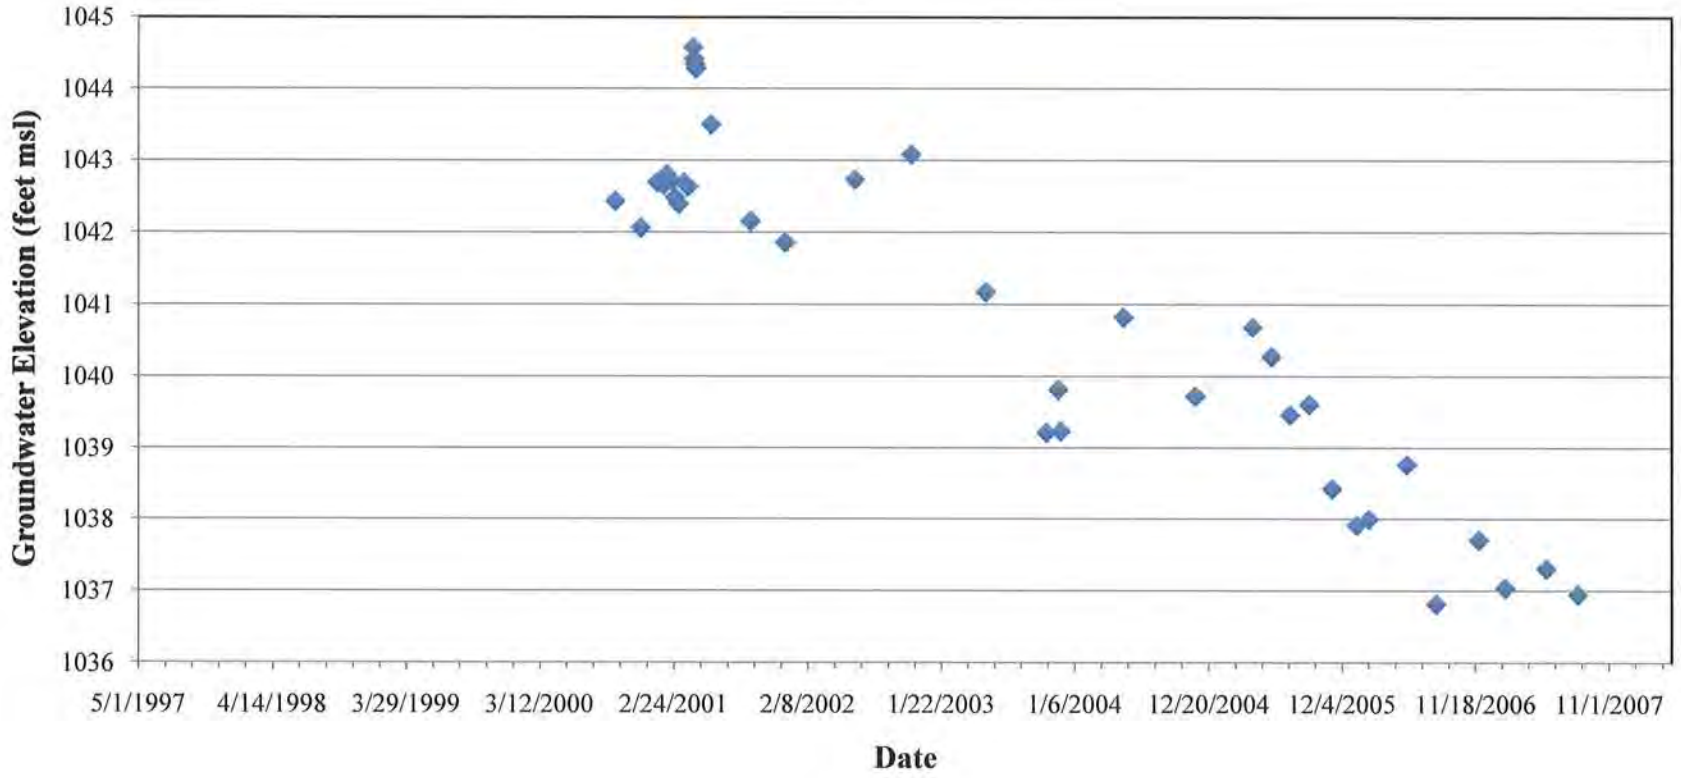
Groundwater Elevations in Well GM-64A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 33-43 Feet Below Ground Surface



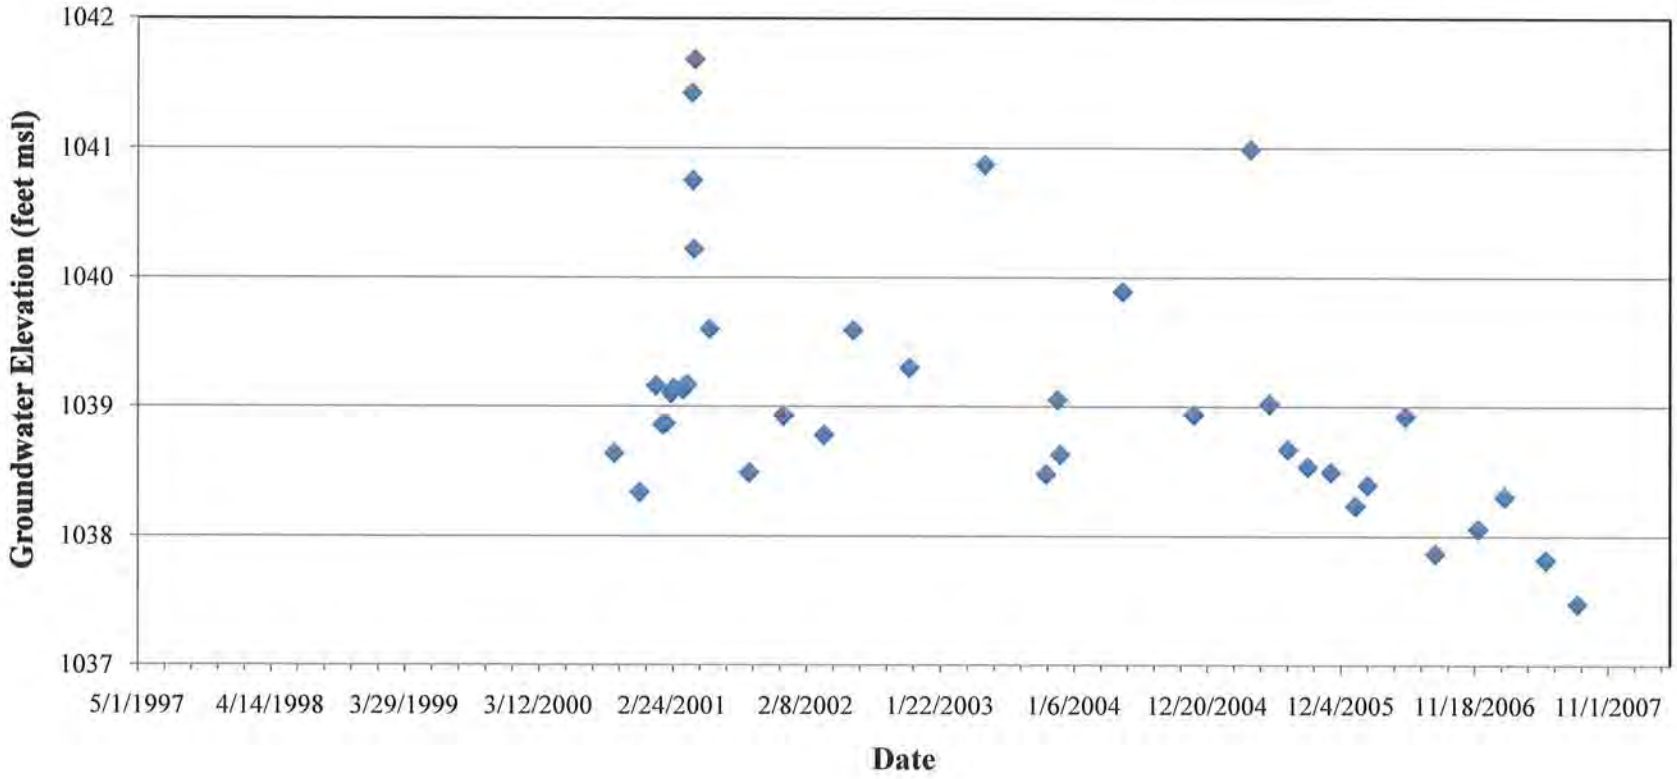
Groundwater Elevations in Well GM-64B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 117-122 Feet Below Ground Surface



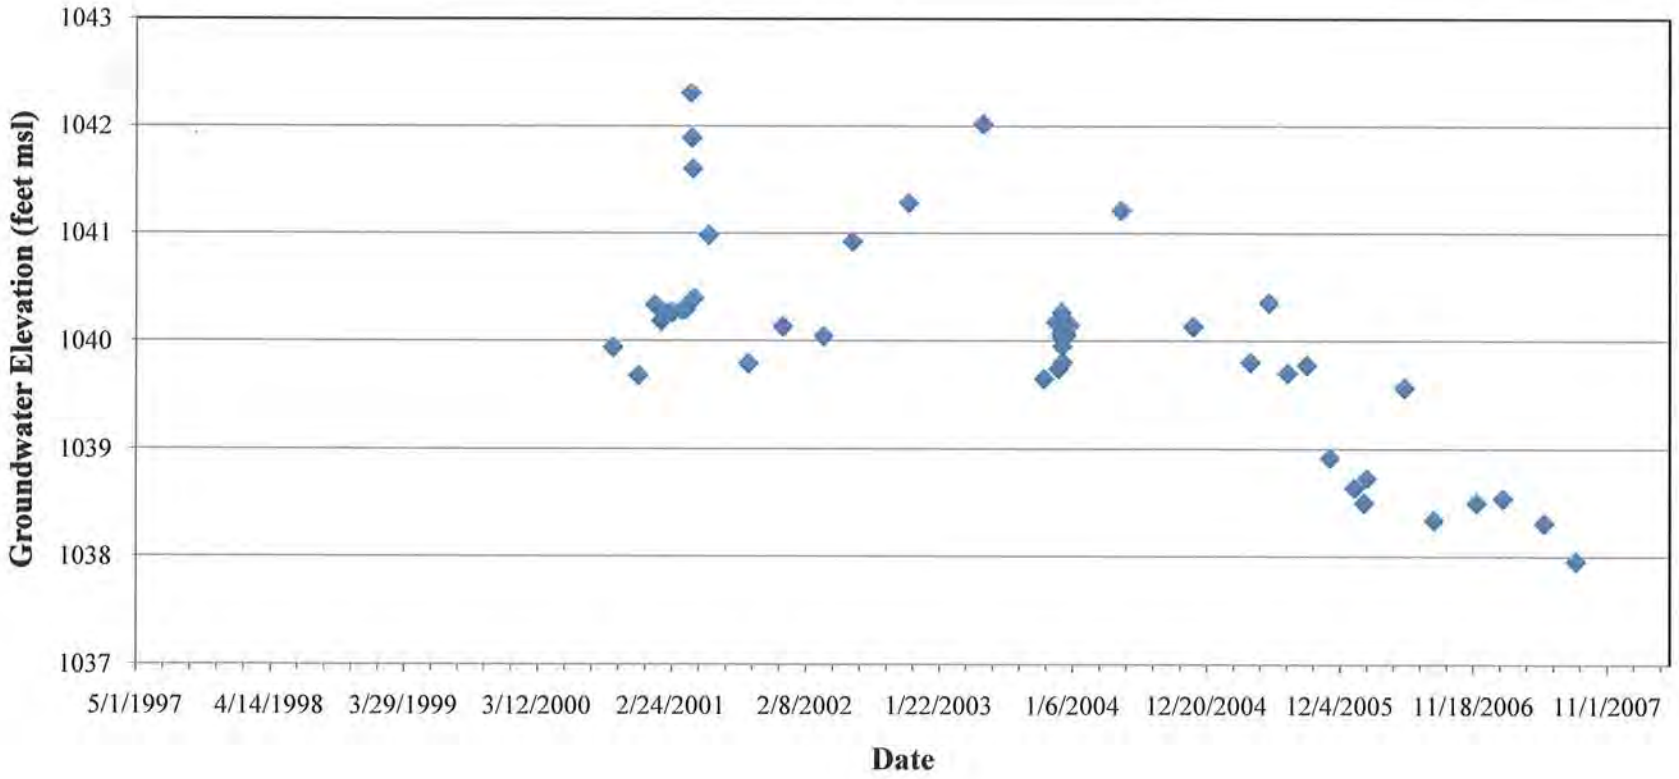
Groundwater Elevations in Well GM-65
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 120-130 Feet Below Ground Surface



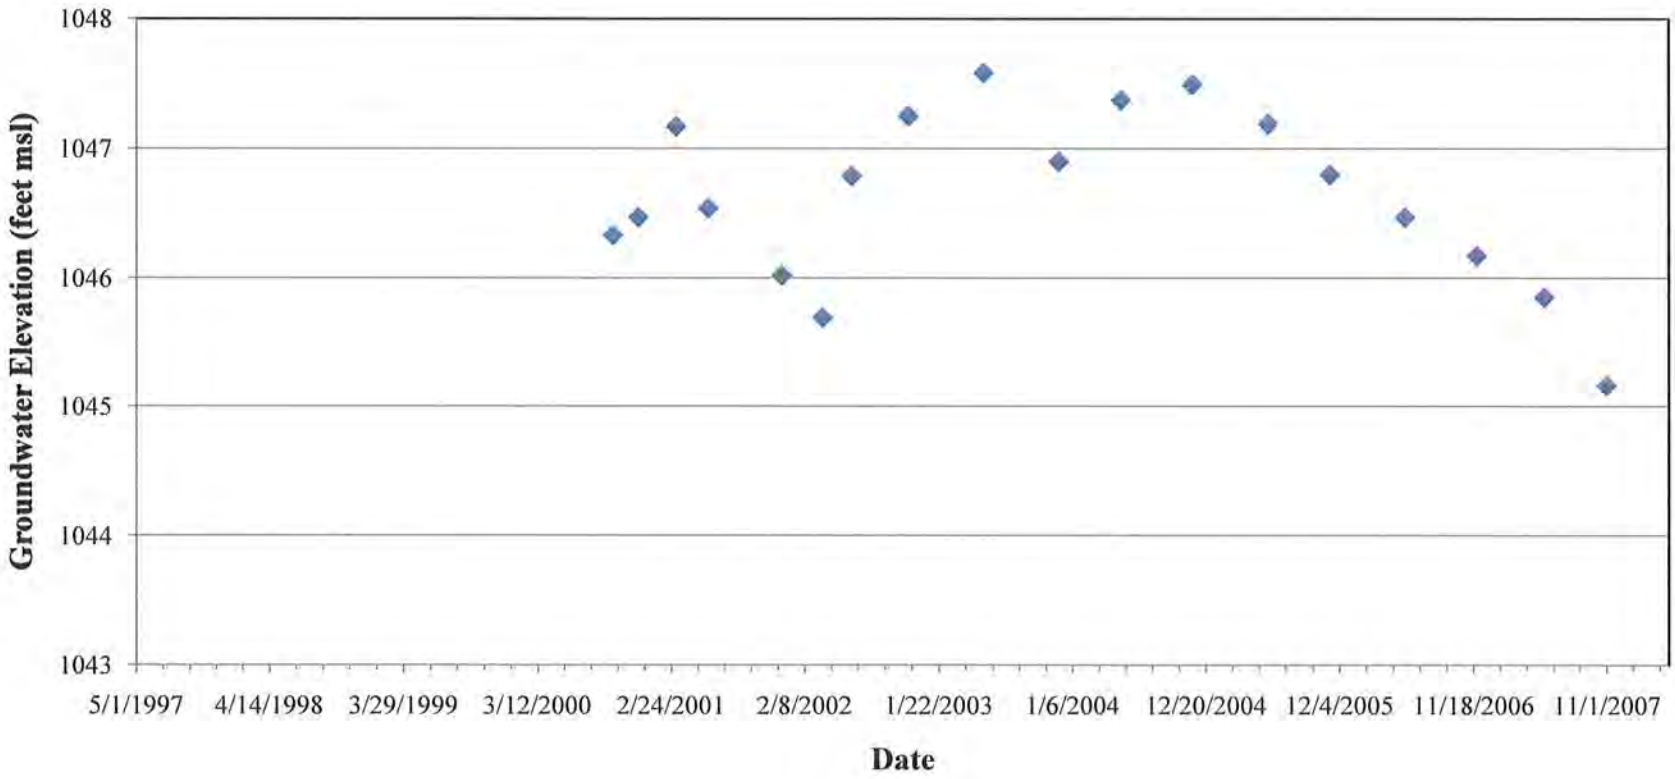
Groundwater Elevations in Well GM-66A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 27-37 Feet Below Ground Surface



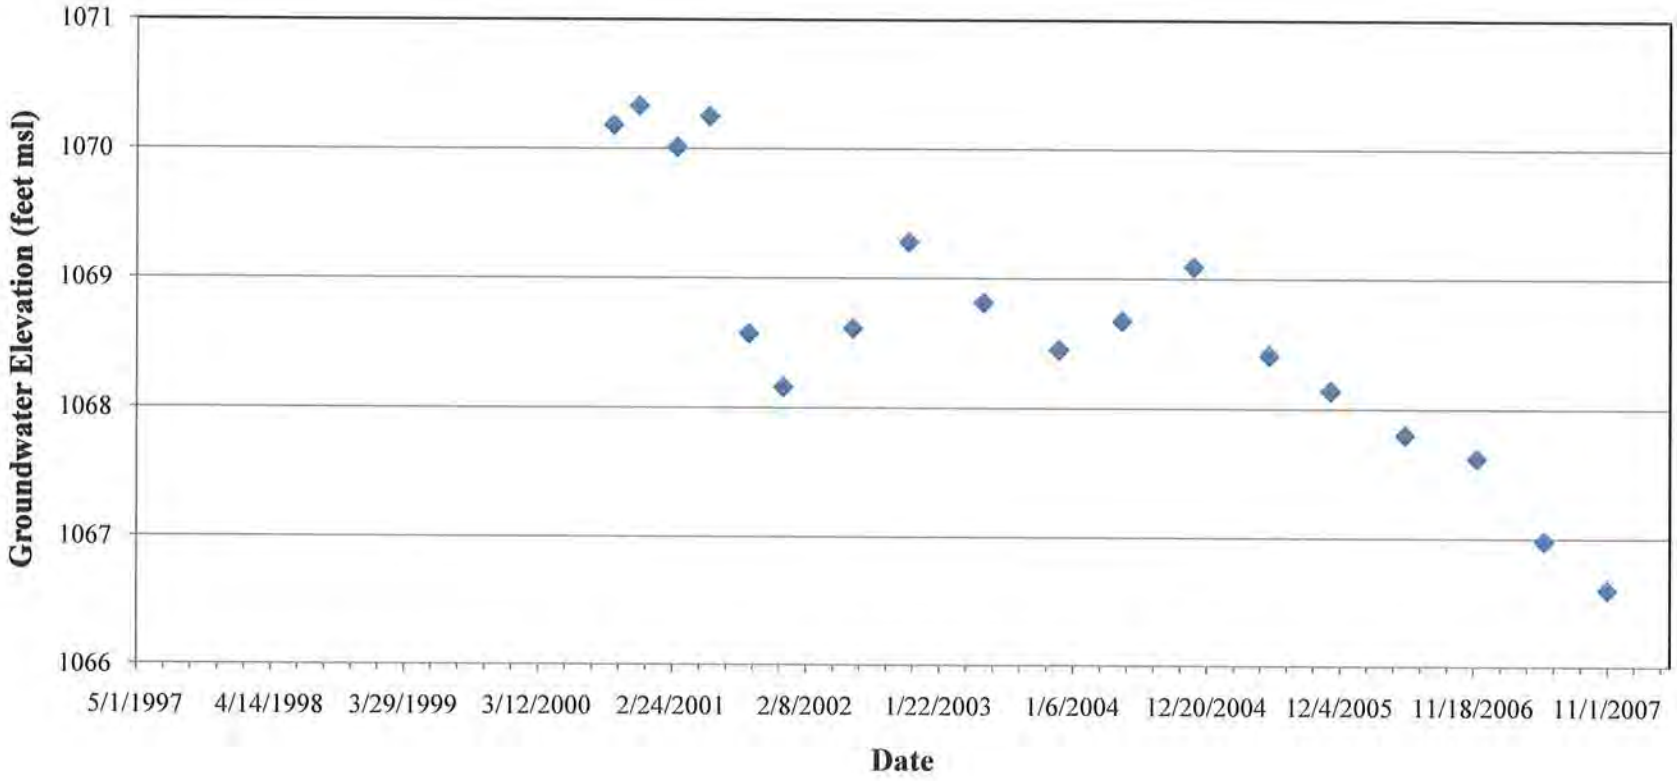
Groundwater Elevations in Well GM-66B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 125-135 Feet Below Ground Surface



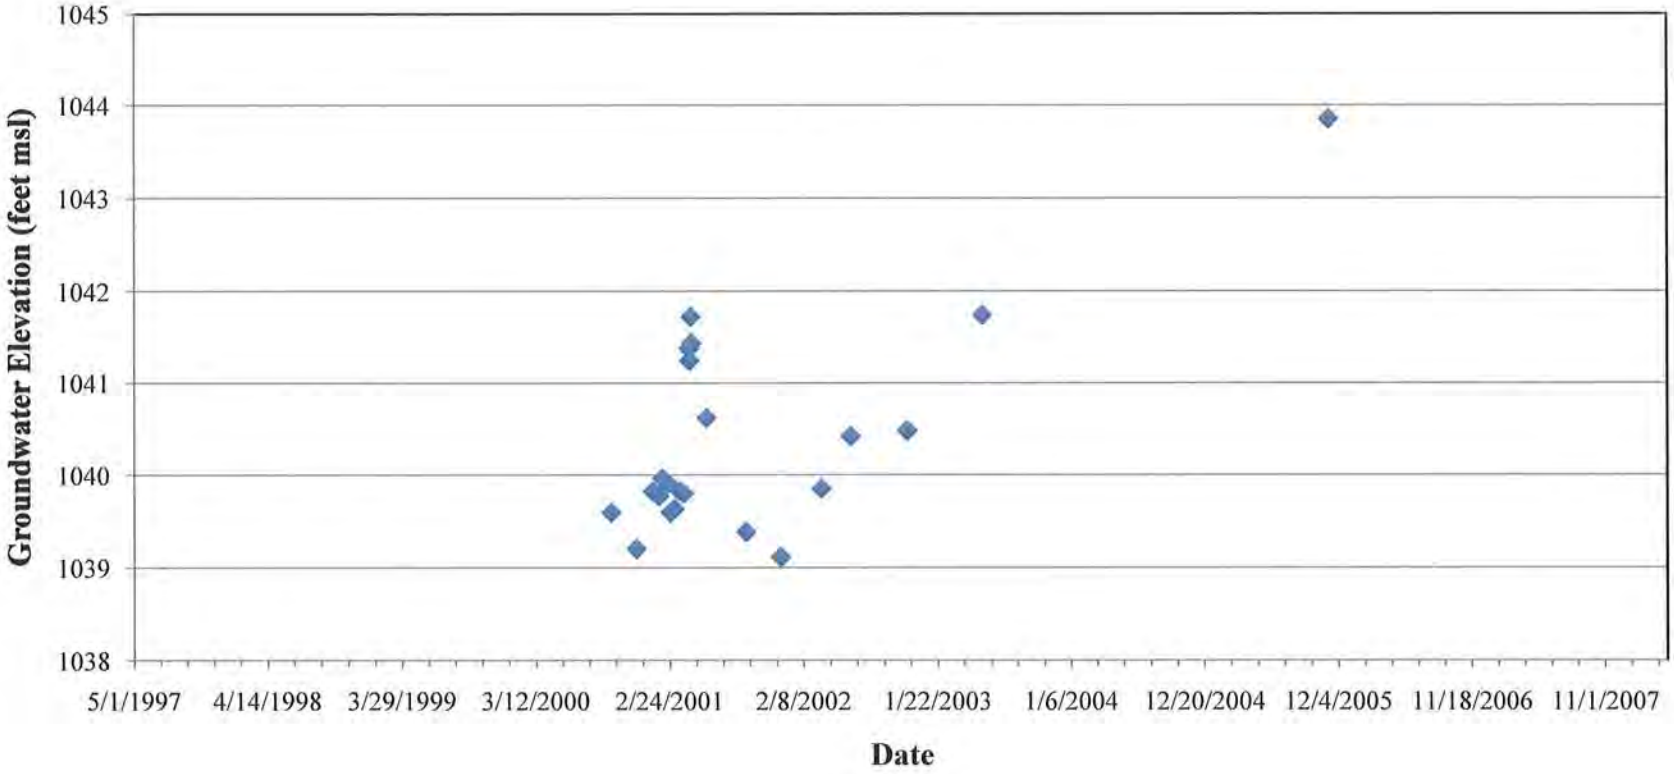
Groundwater Elevations in Well GM-67
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 122-127 Feet Below Ground Surface



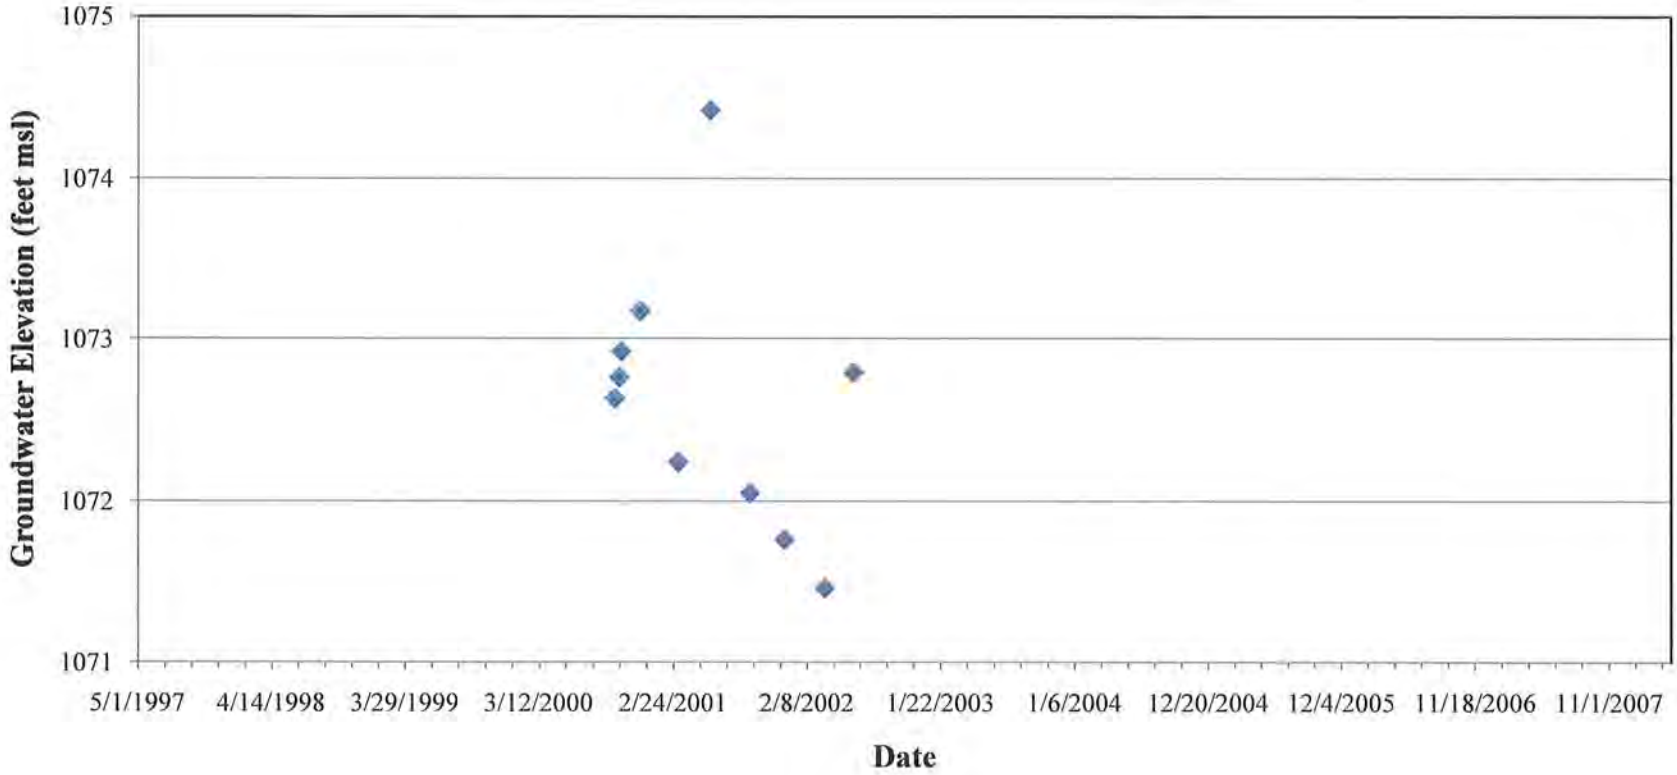
Groundwater Elevations in Well GM-68
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 140-150 Feet Below Ground Surface



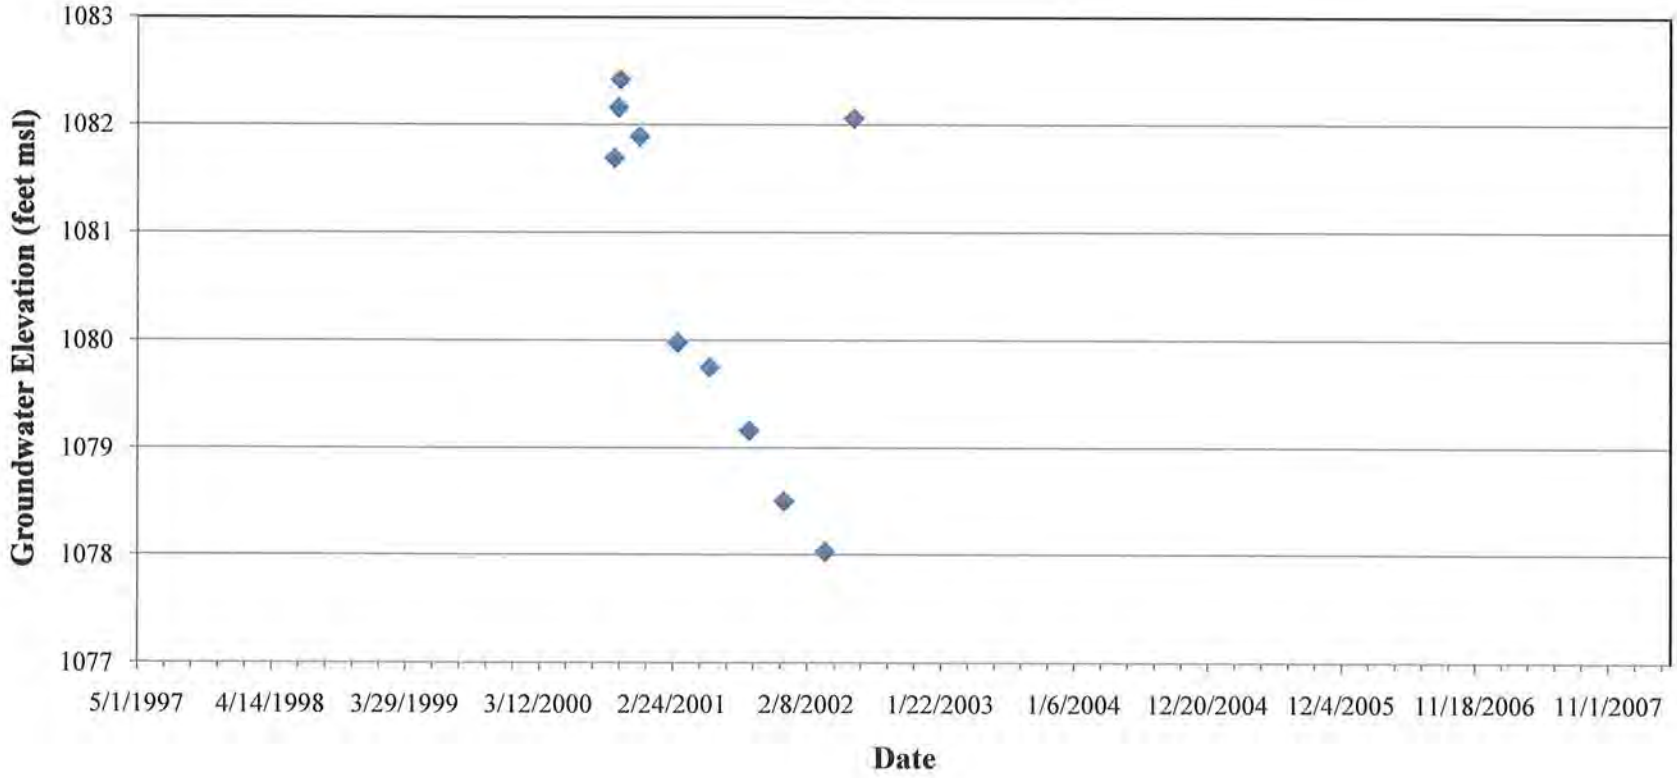
Groundwater Elevations in Well GM-69
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 59-69 Feet Below Ground Surface



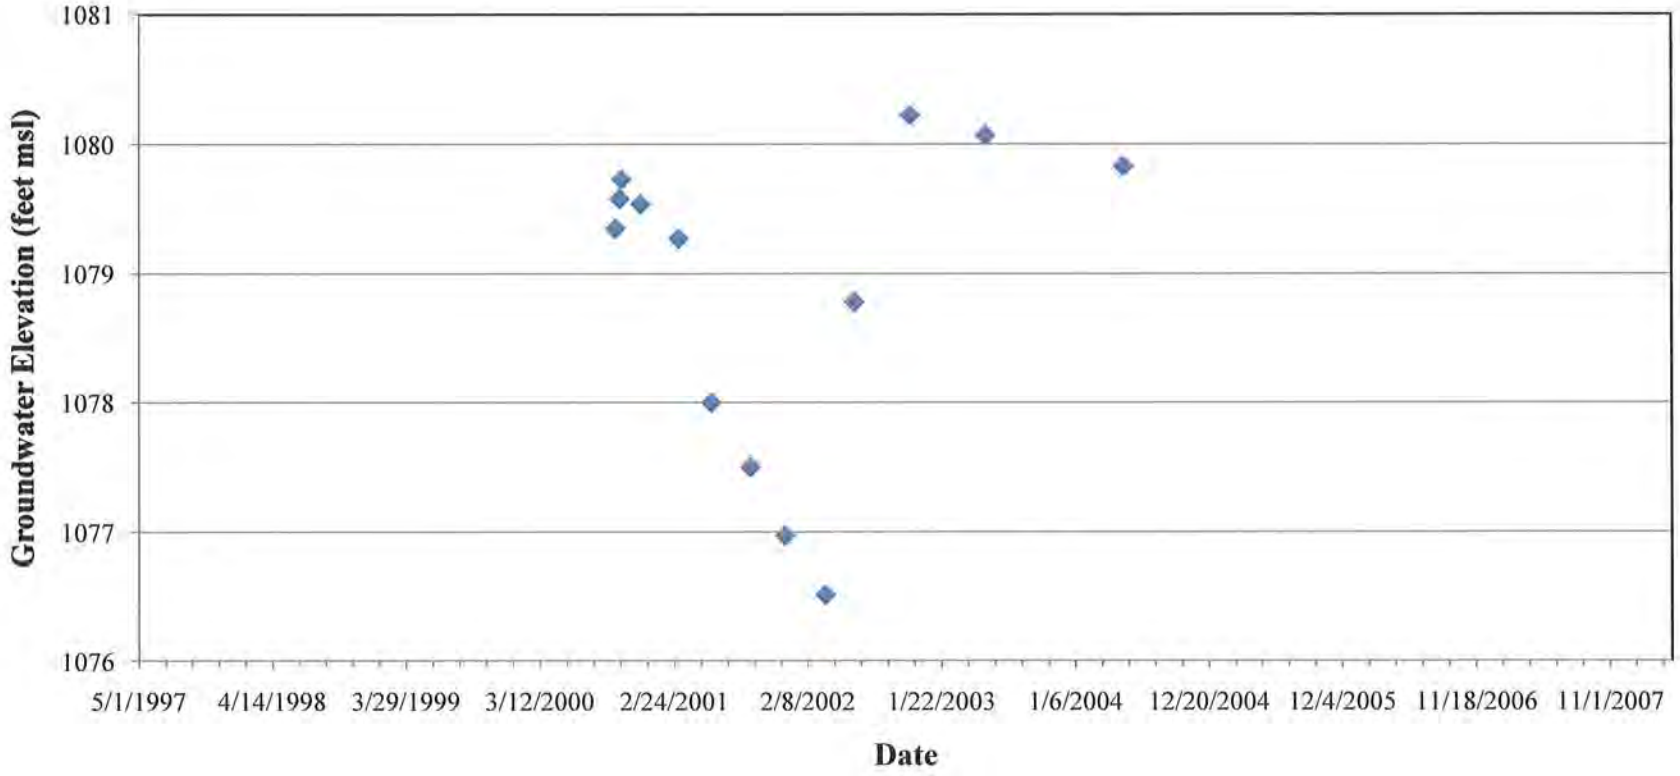
Groundwater Elevations in Well GM-70
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 42-52 Feet Below Ground Surface



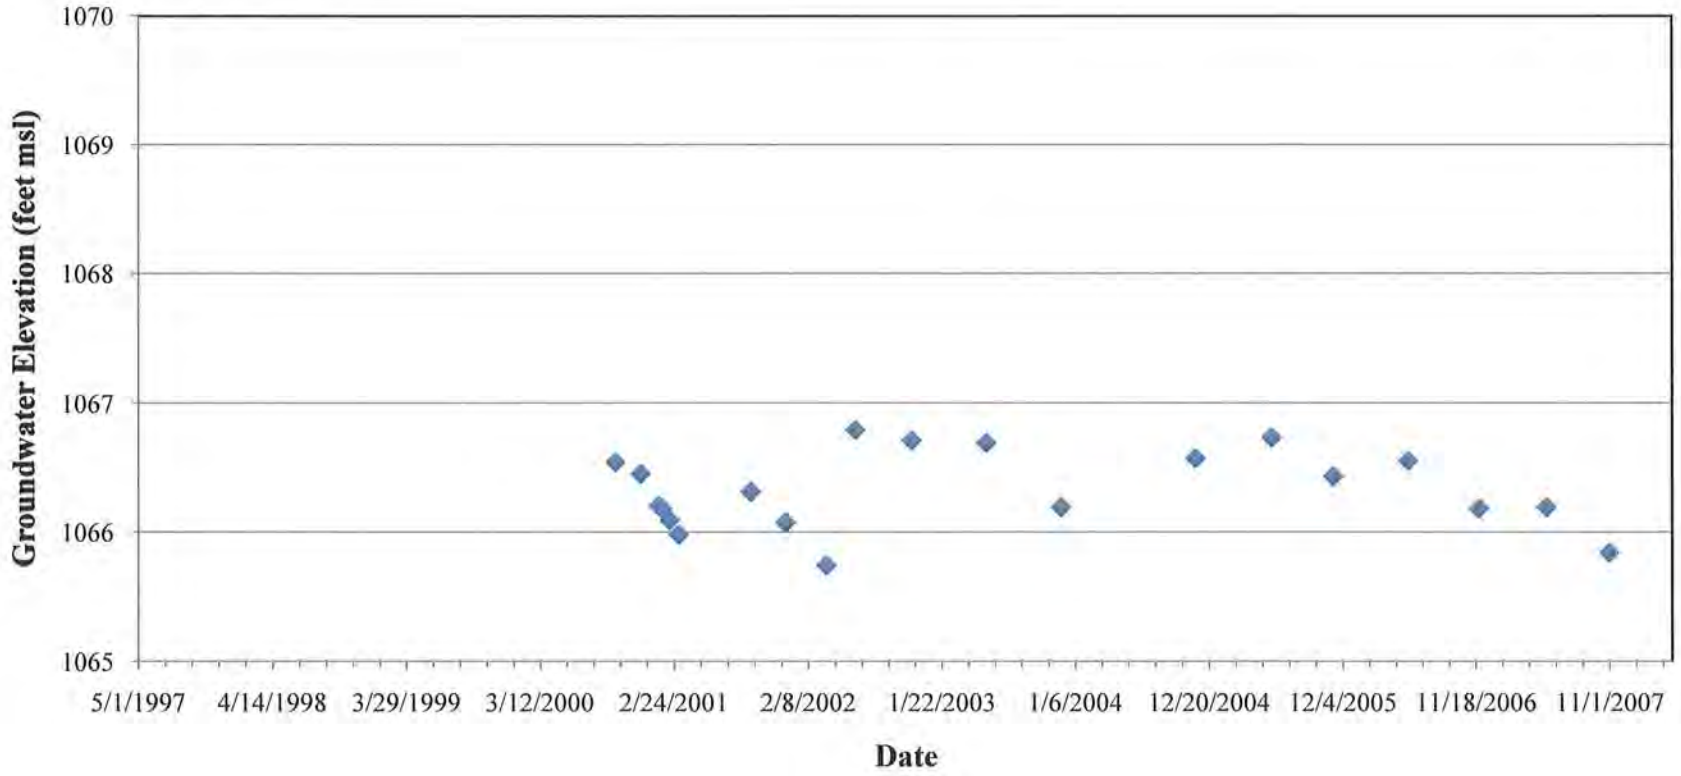
Groundwater Elevations in Well GM-71
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 39-49 Feet Below Ground Surface



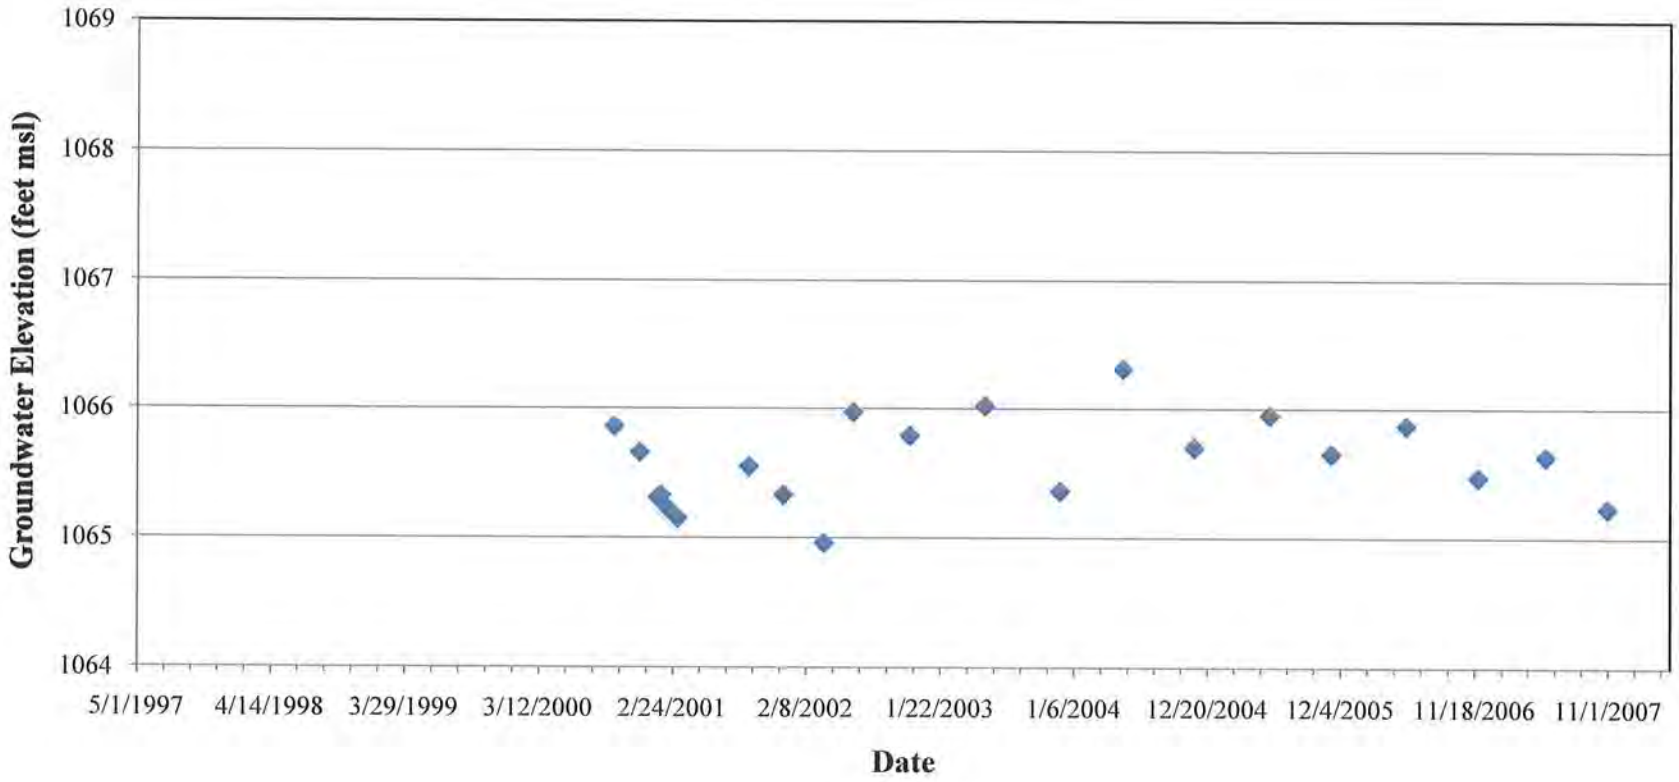
Groundwater Elevations in Well GM-72
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 43-53 Feet Below Ground Surface



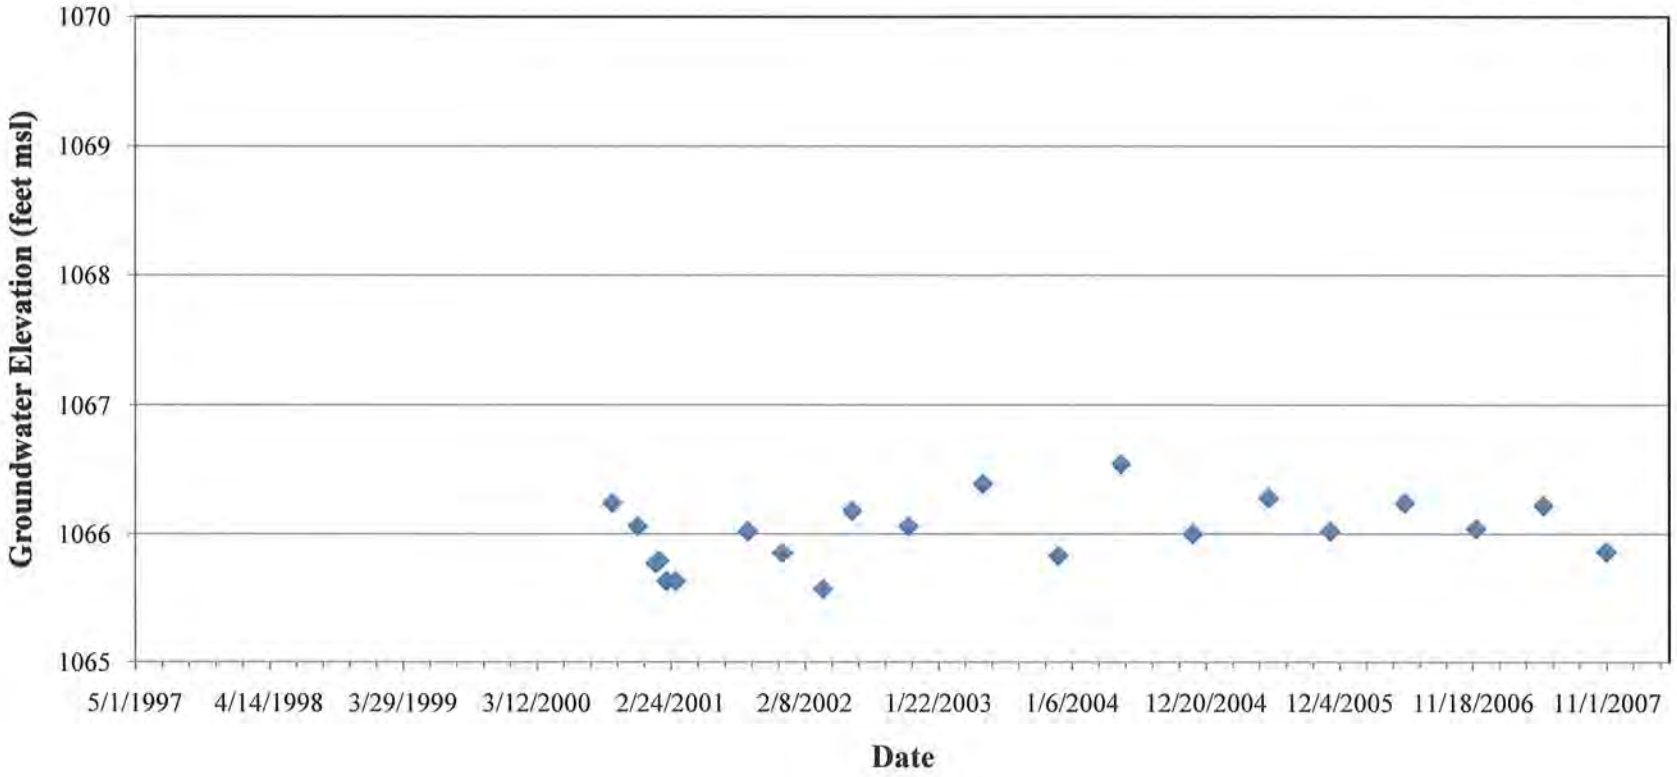
Groundwater Elevations in Well GM-73
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 42-52 Feet Below Ground Surface



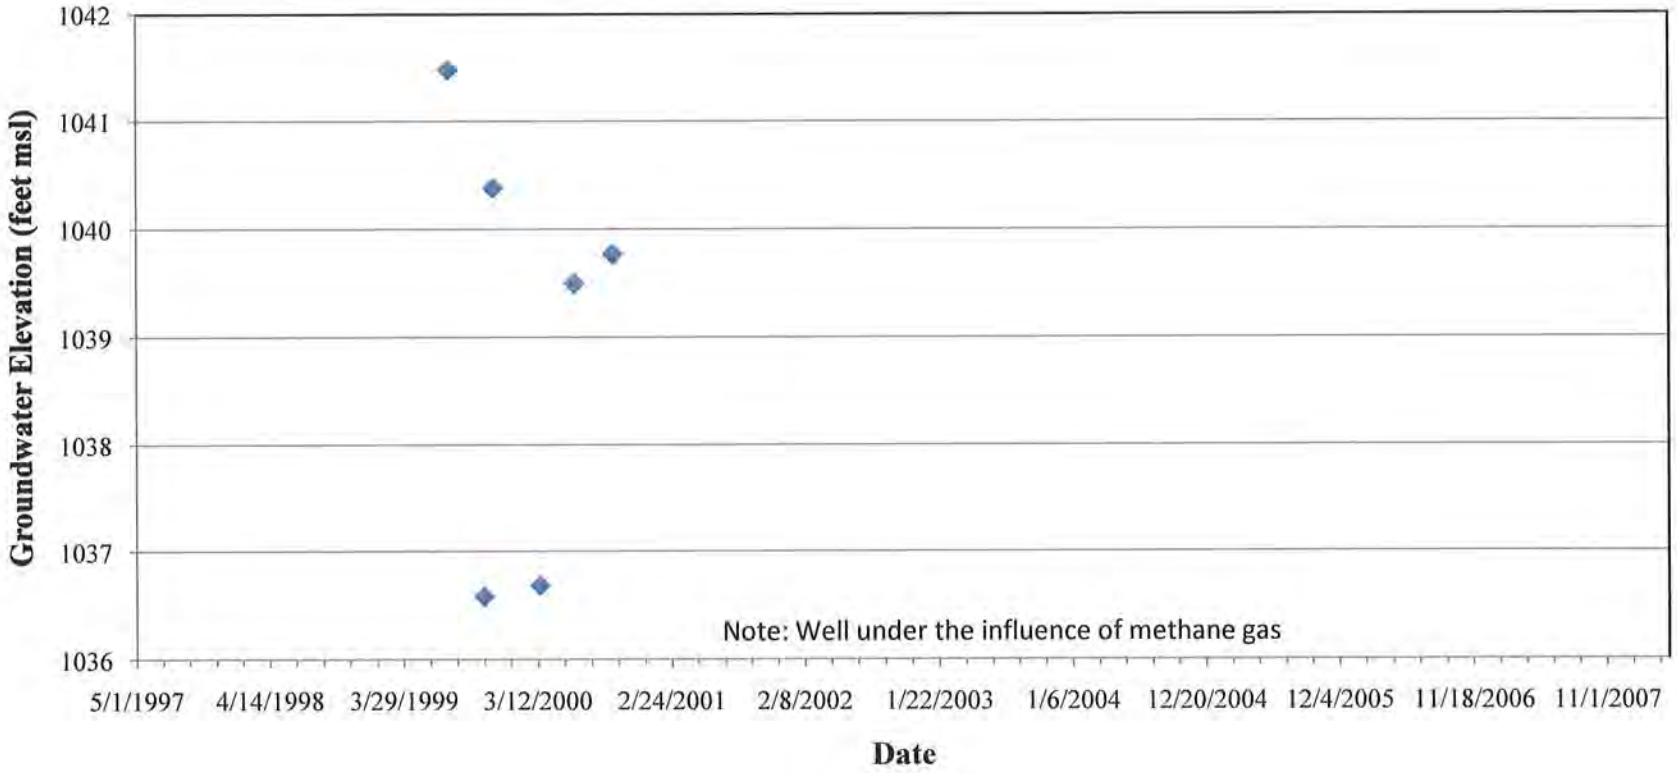
Groundwater Elevations in Well GM-74
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 34-44 Feet Below Ground Surface



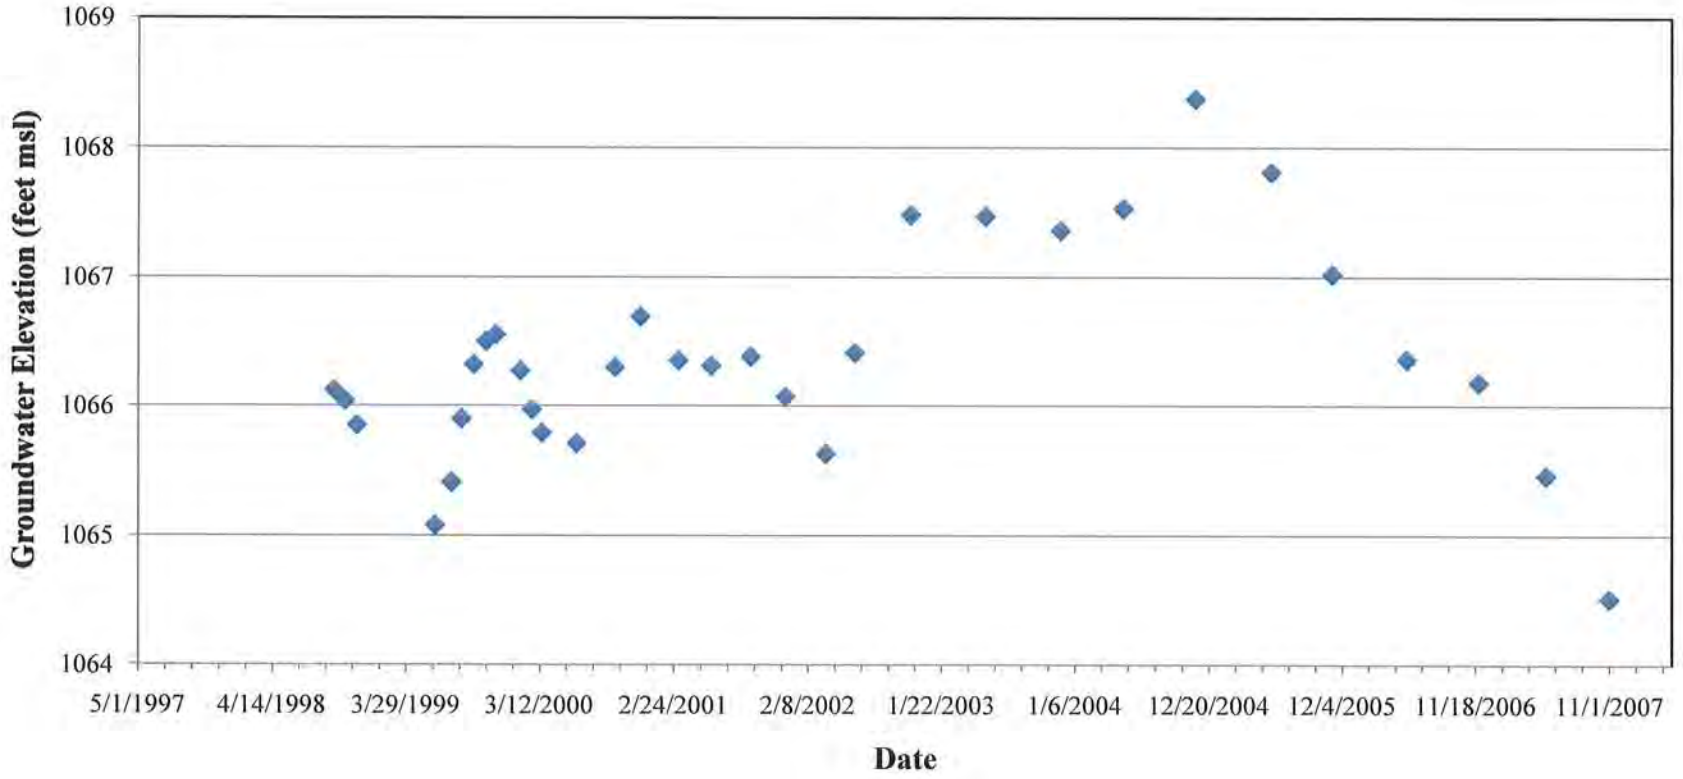
Groundwater Elevations in Well GM-75
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 24-34 Feet Below Ground Surface



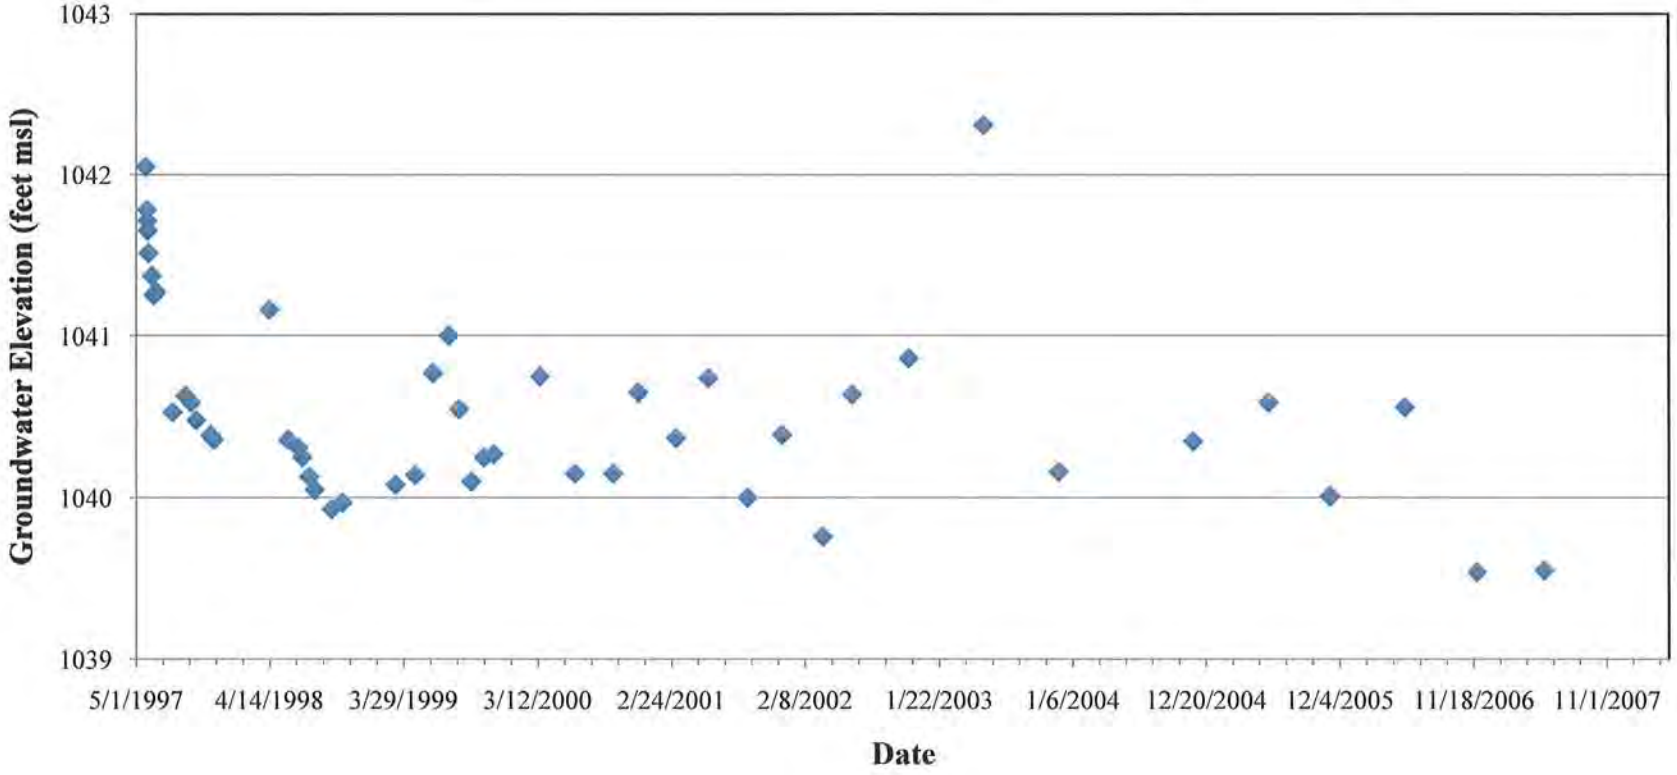
Groundwater Elevations in Well GM-100
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 65.5-75.5 Feet Below Ground Surface



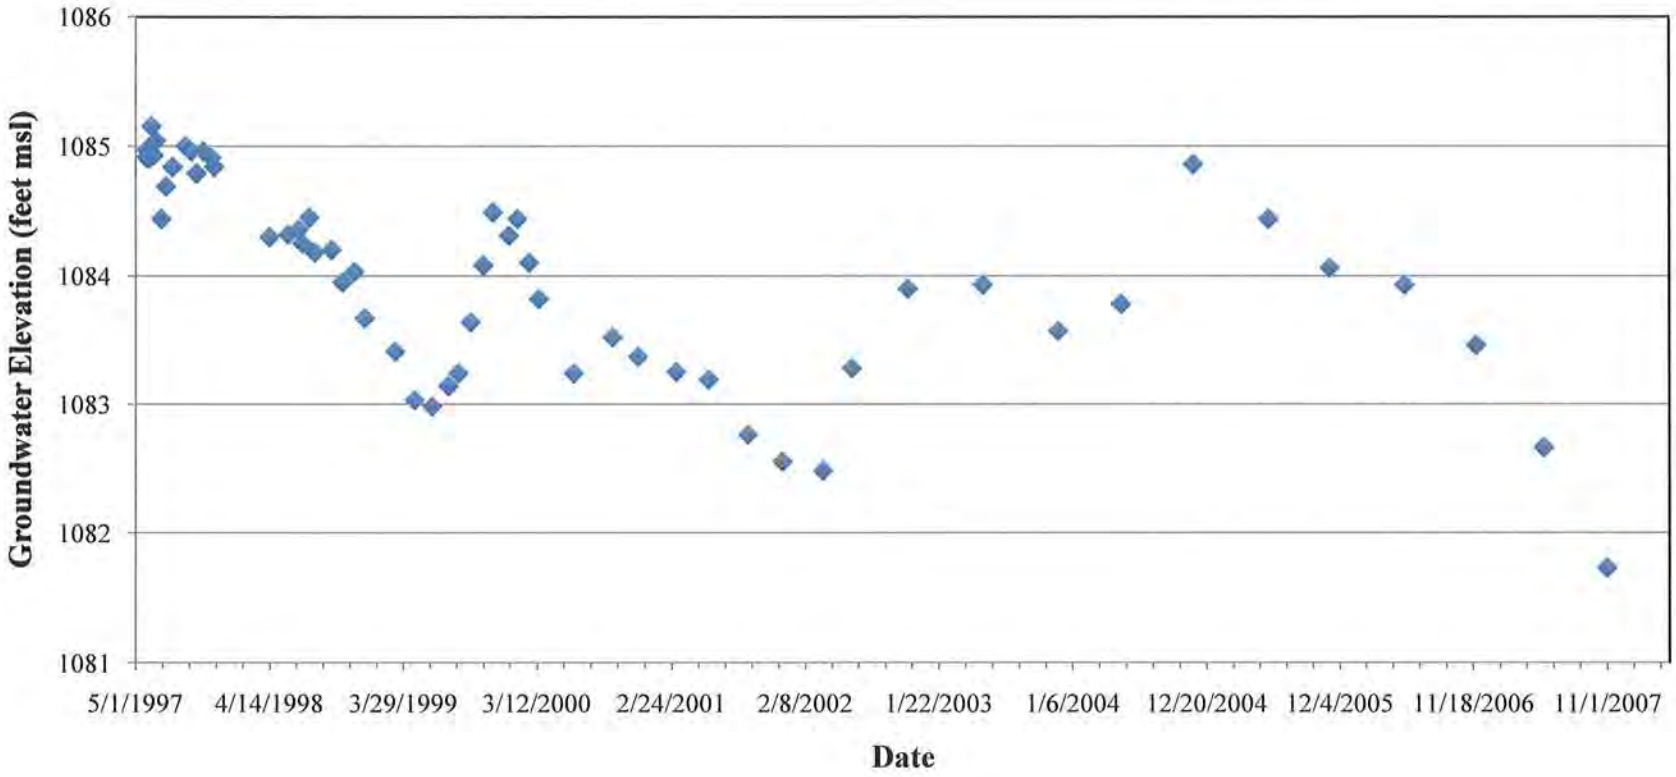
Groundwater Elevations in Well GM-118D
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 54-59 Feet Below Ground Surface



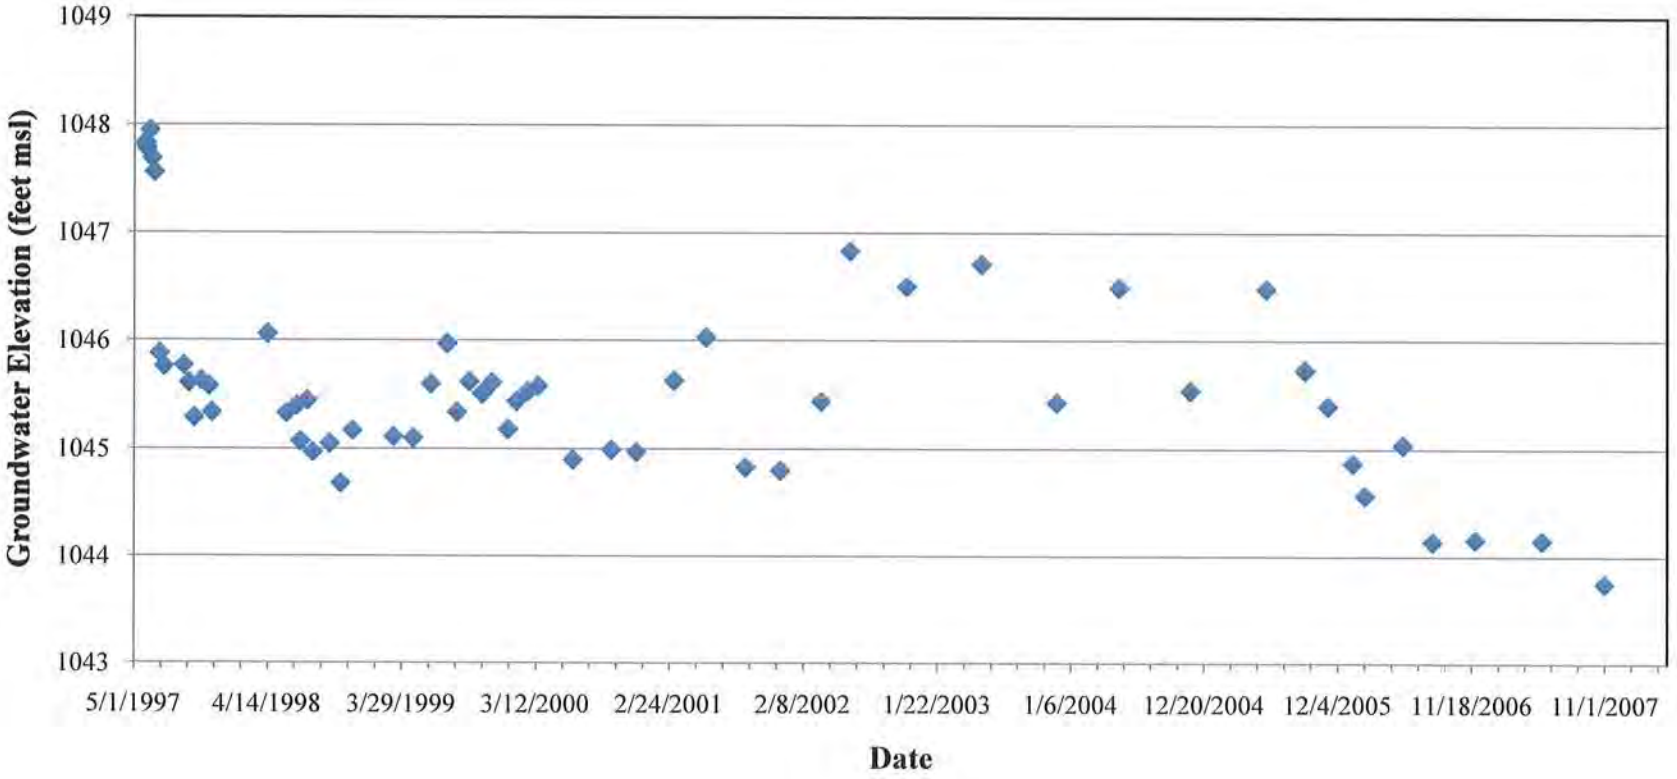
Groundwater Elevations in Well BR-1
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 206-226 Feet Below Ground Surface



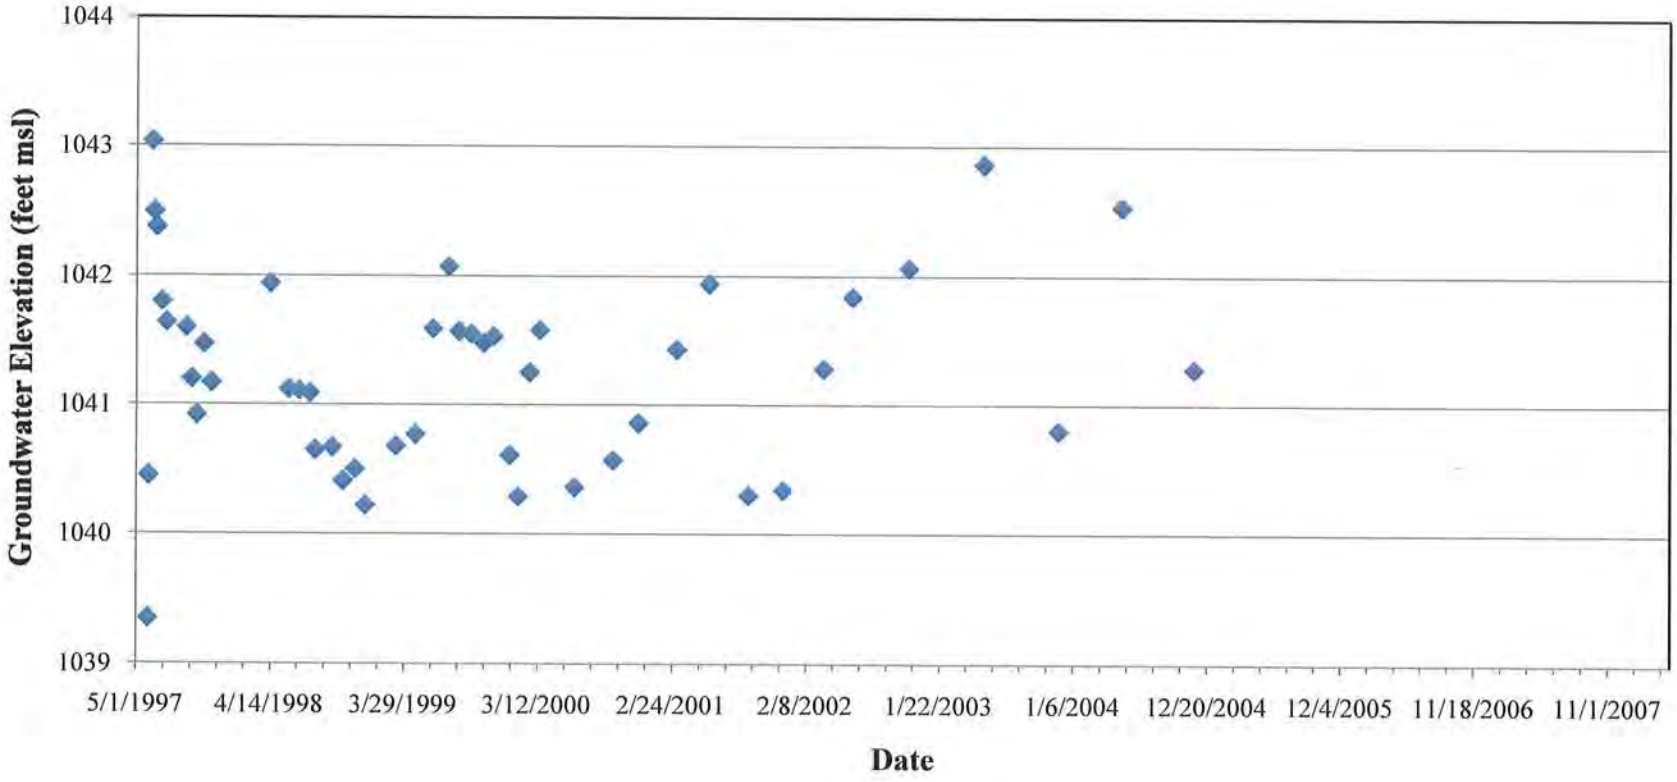
Groundwater Elevations in Well BR-2
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 75-85 Feet Below Ground Surface



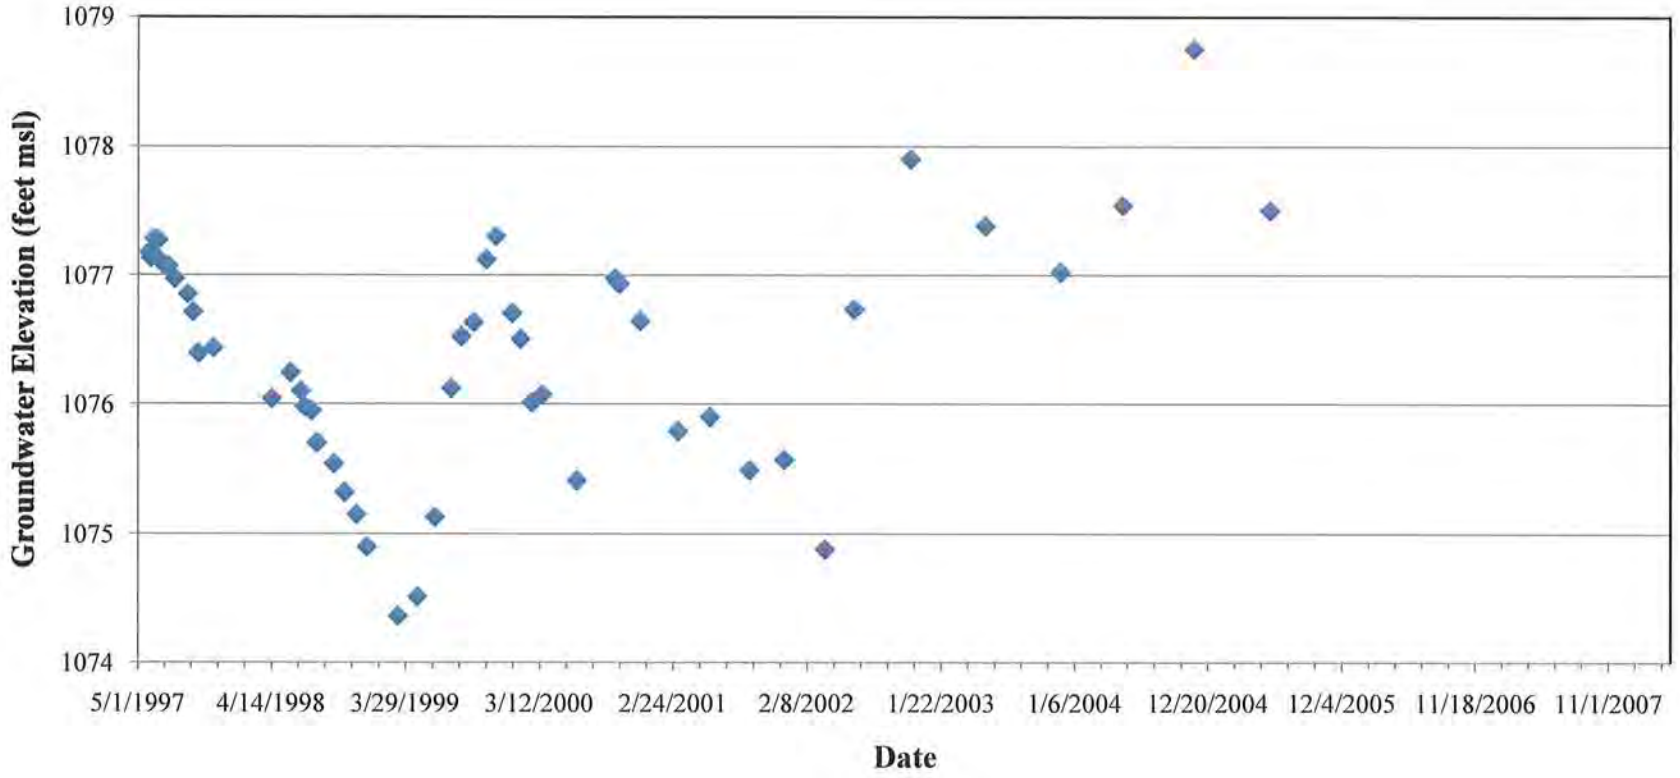
Groundwater Elevations in Well BR-3
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 122-127 Feet Below Ground Surface



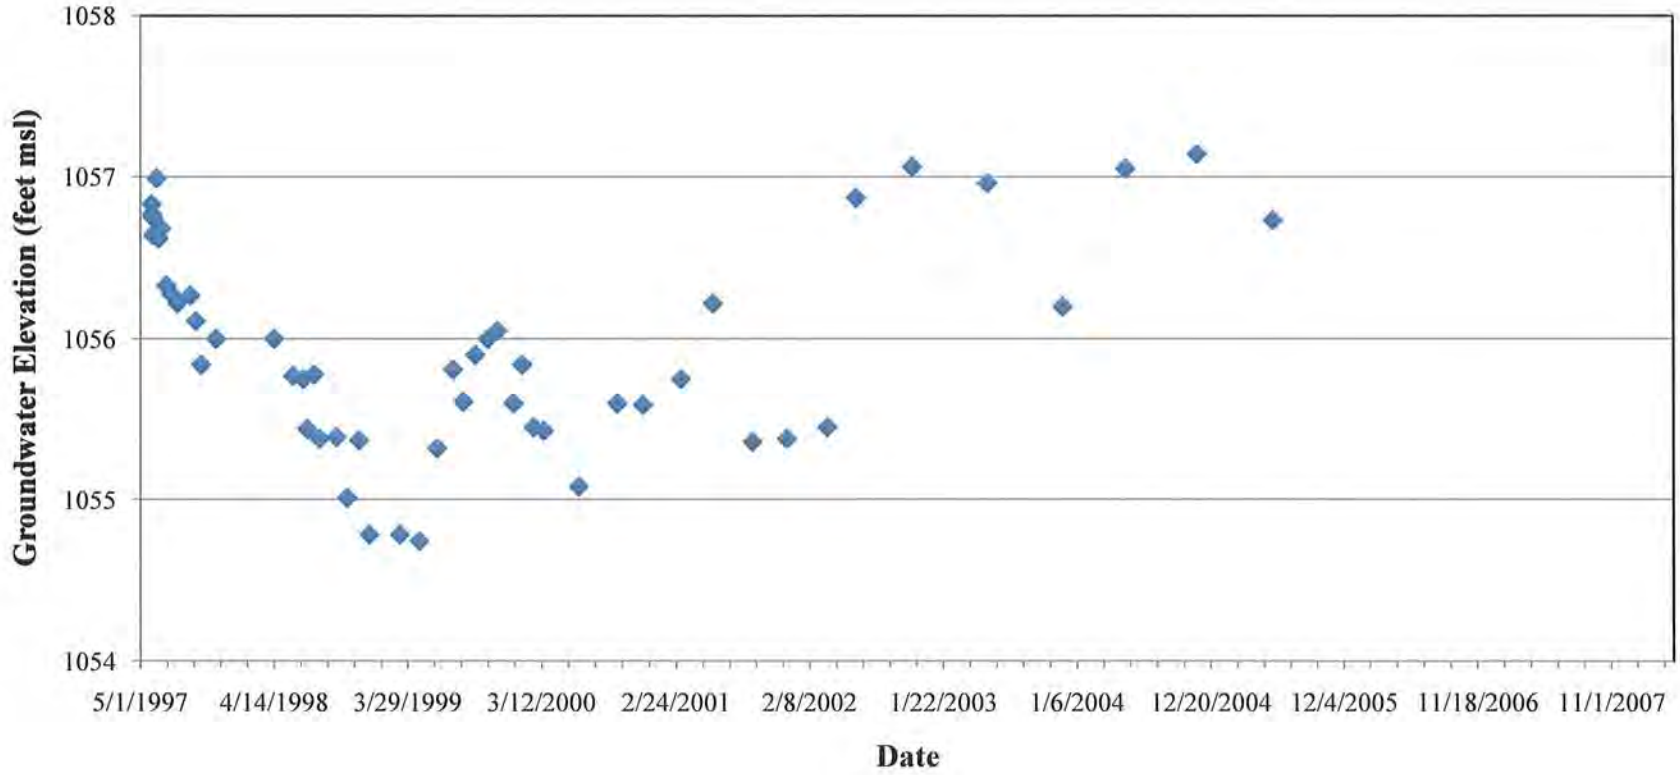
Groundwater Elevations in Well BR-4
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 95-105 Feet Below Ground Surface



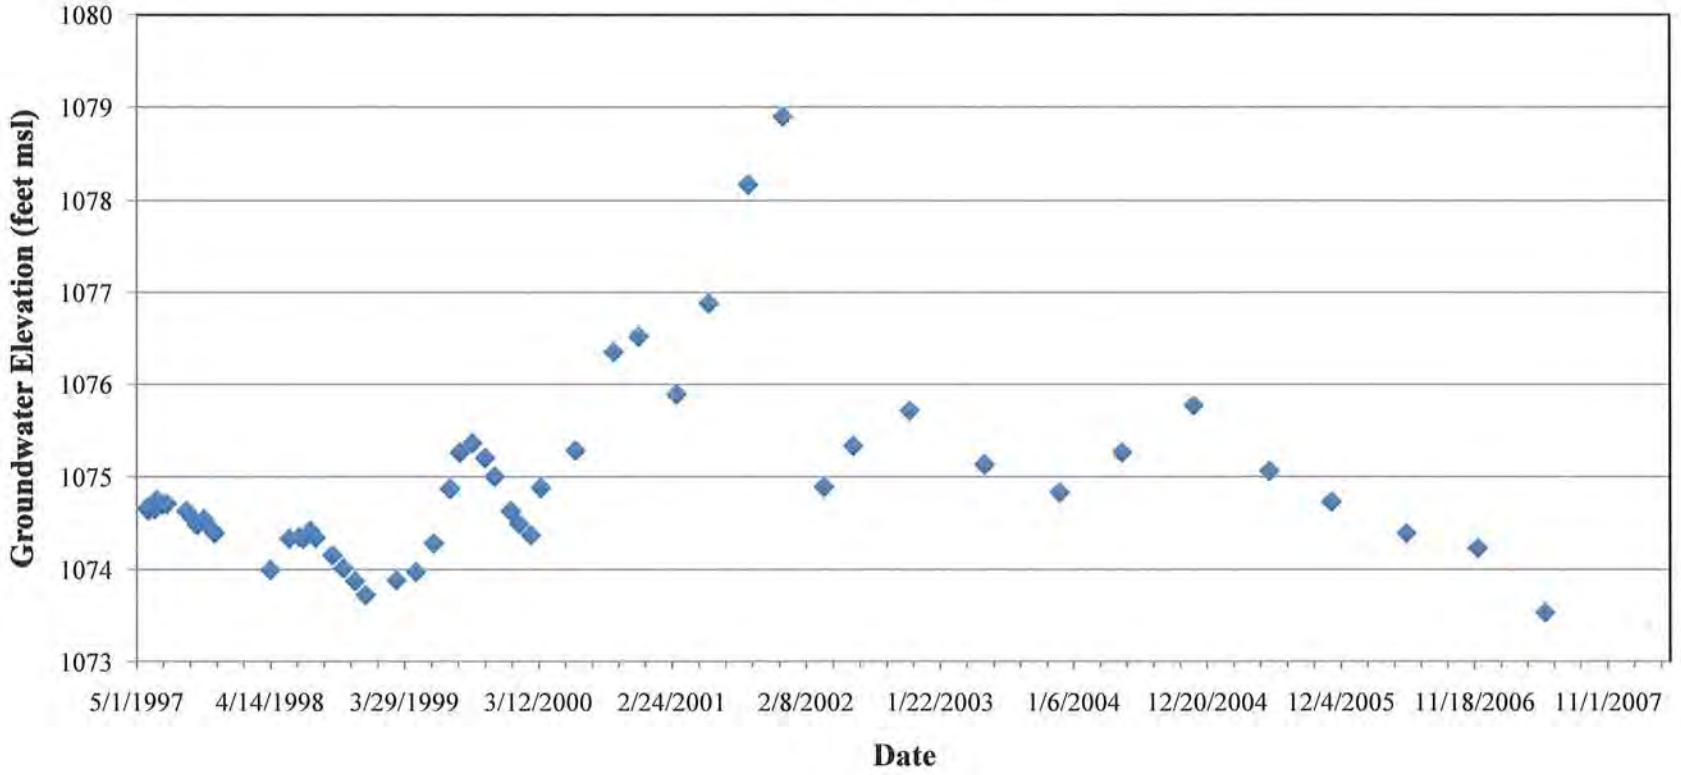
Groundwater Elevations in Well BR-5A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 88-98 Feet Below Ground Surface



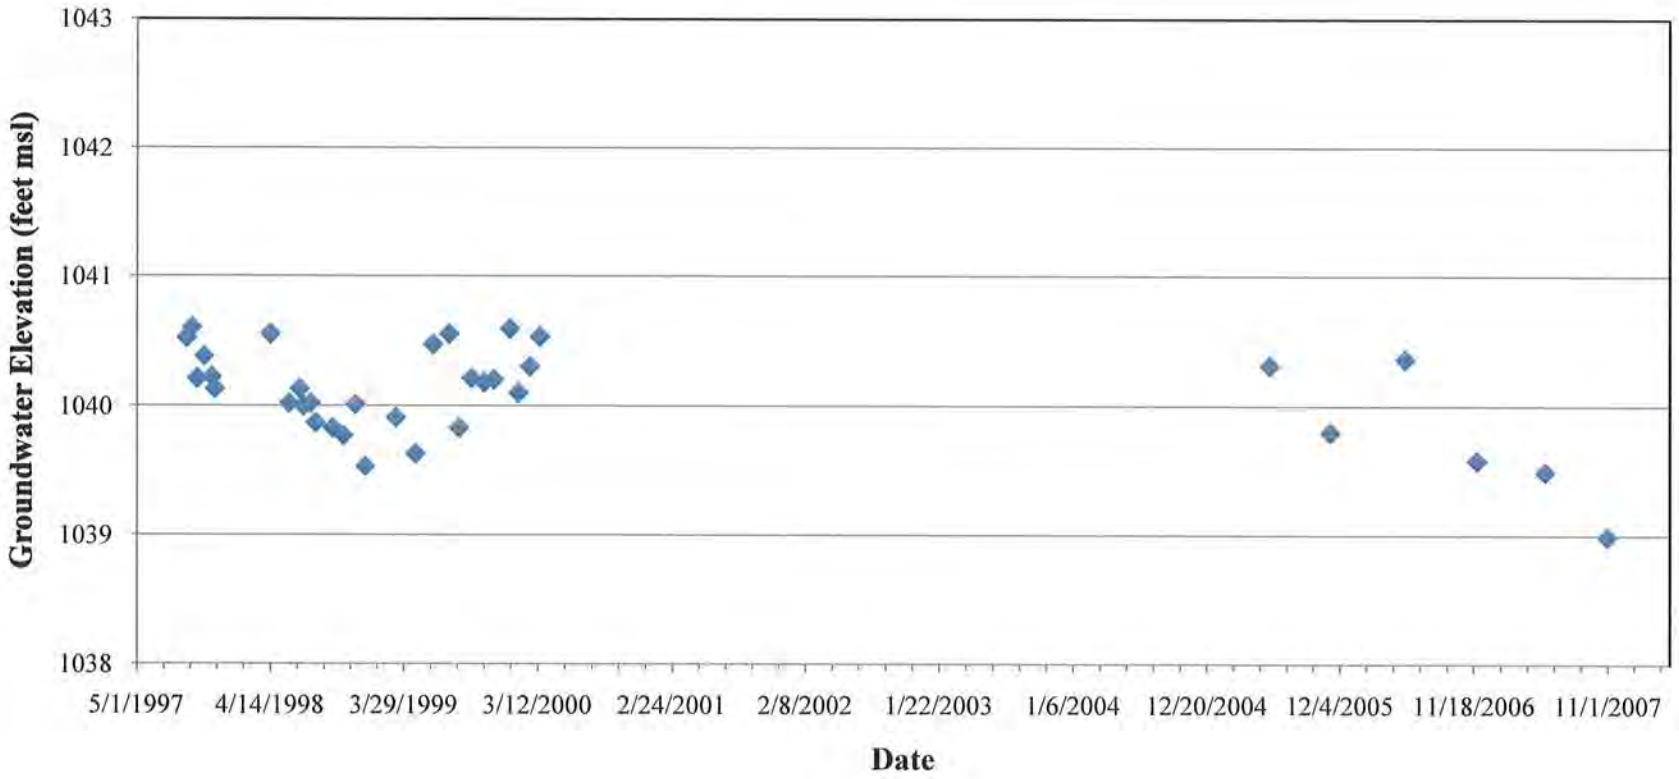
Groundwater Elevations in Well BR-5B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 188-198 Feet Below Ground Surface



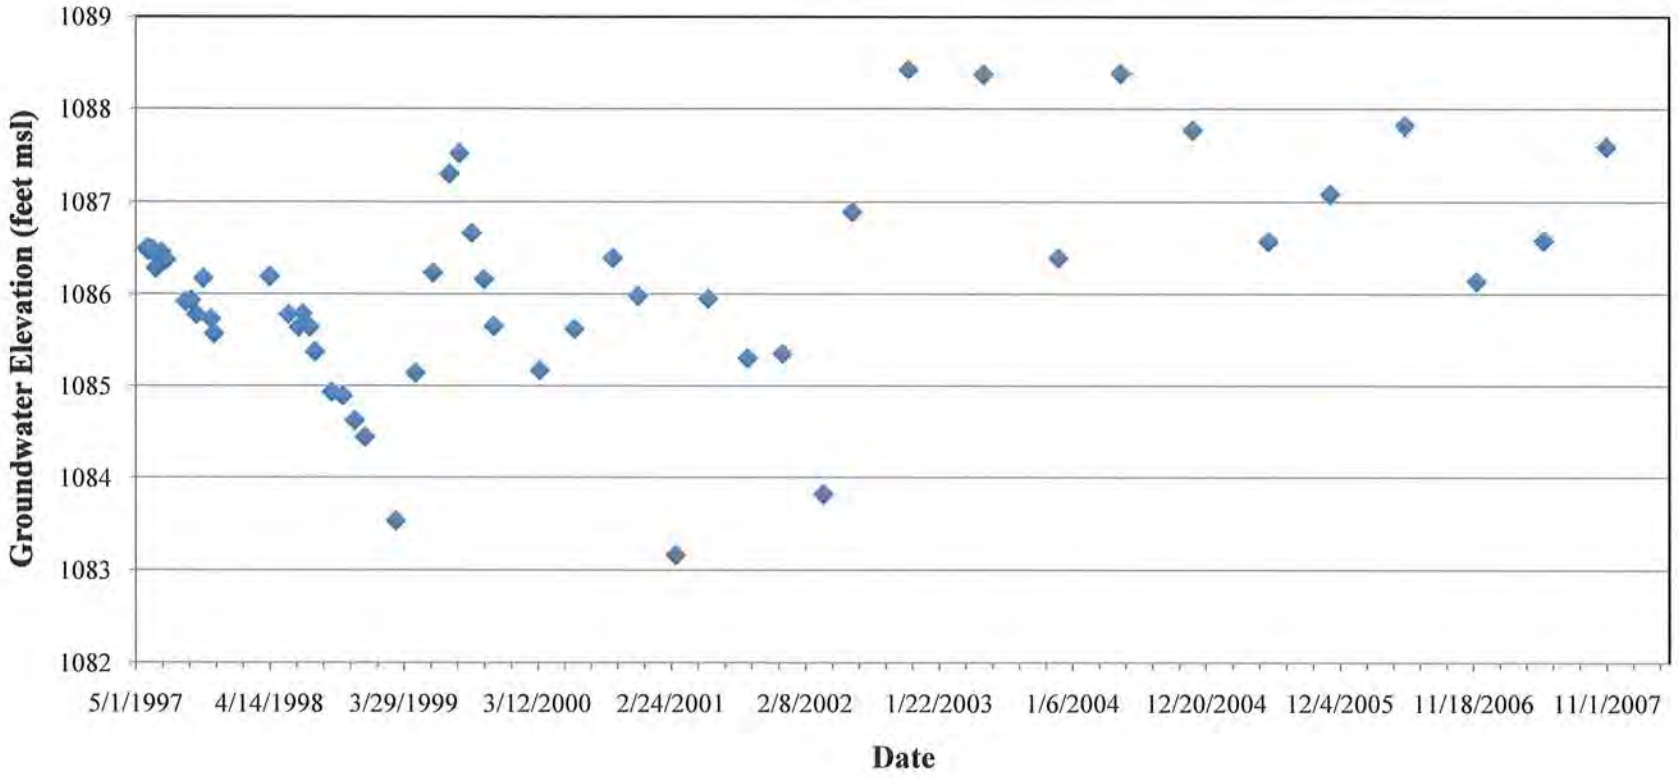
Groundwater Elevations in Well BR-6
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 149-169 Feet Below Ground Surface



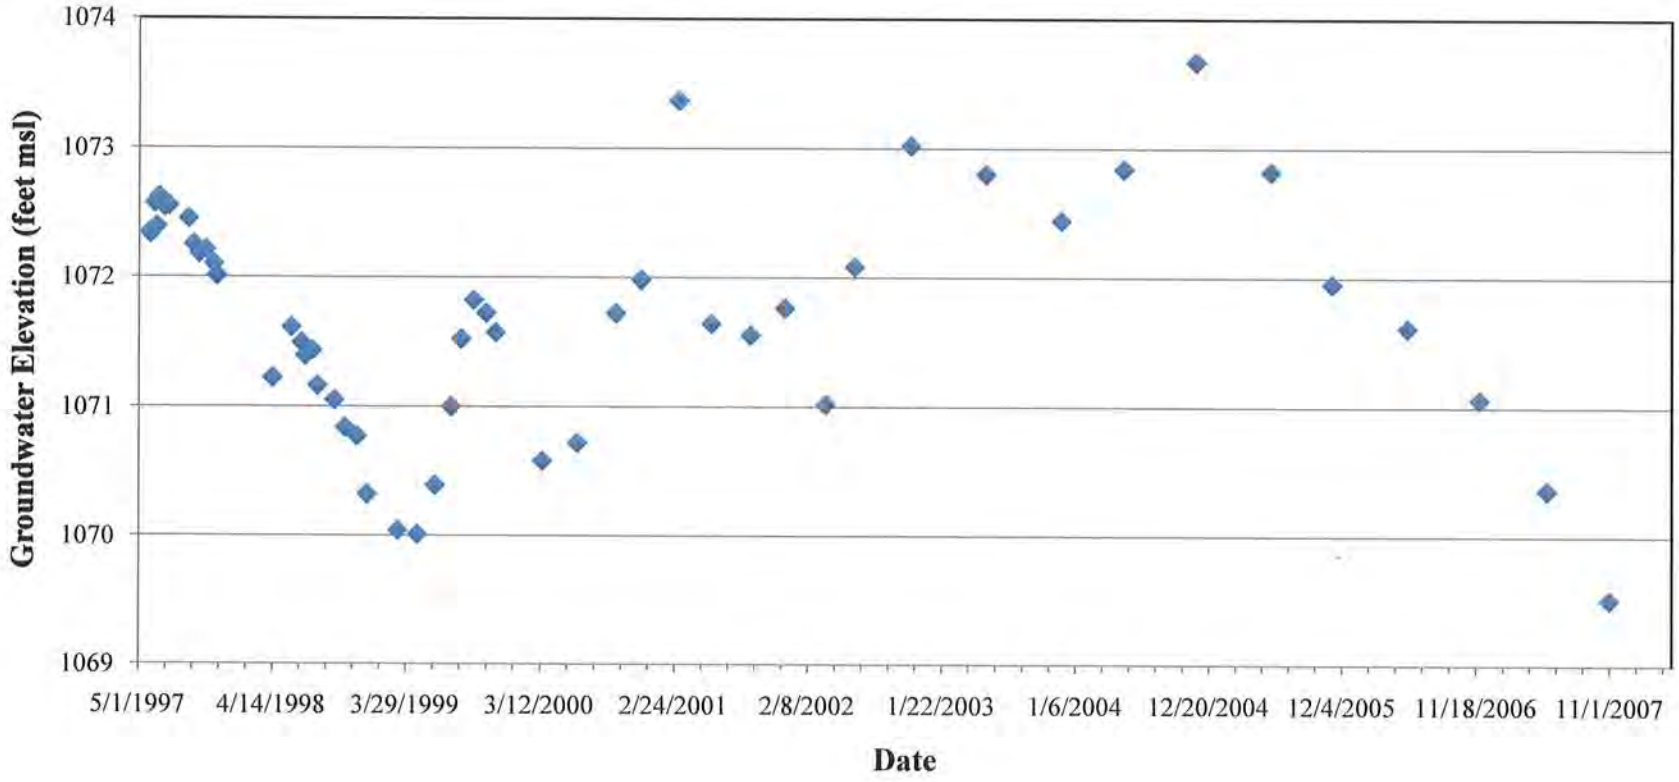
Groundwater Elevations in Well CW-1
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 130-140 Feet Below Ground Surface



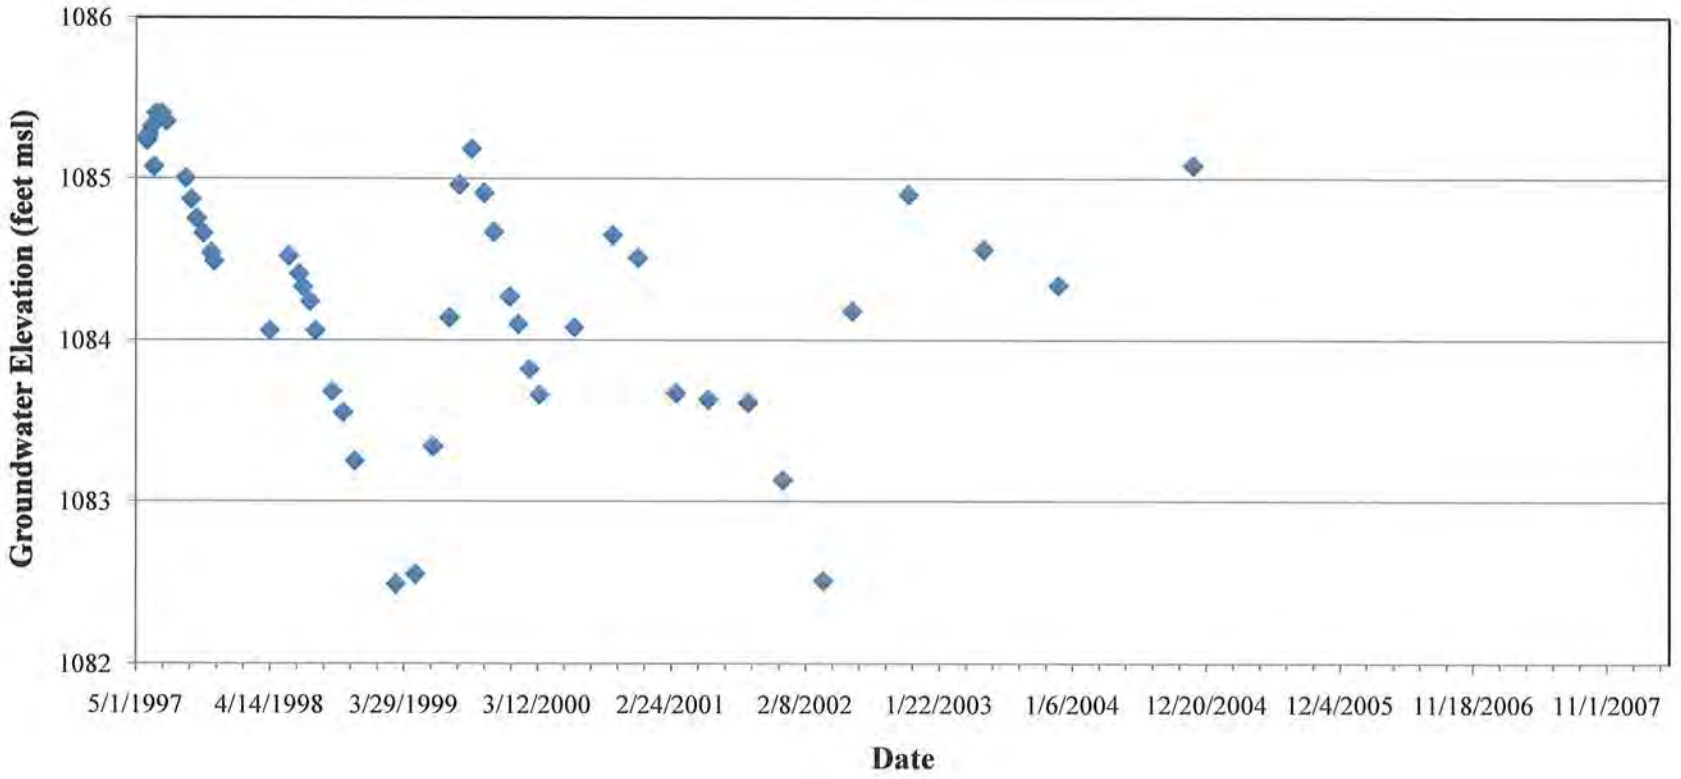
Groundwater Elevations in Well MW-1A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 35-45 Feet Below Ground Surface



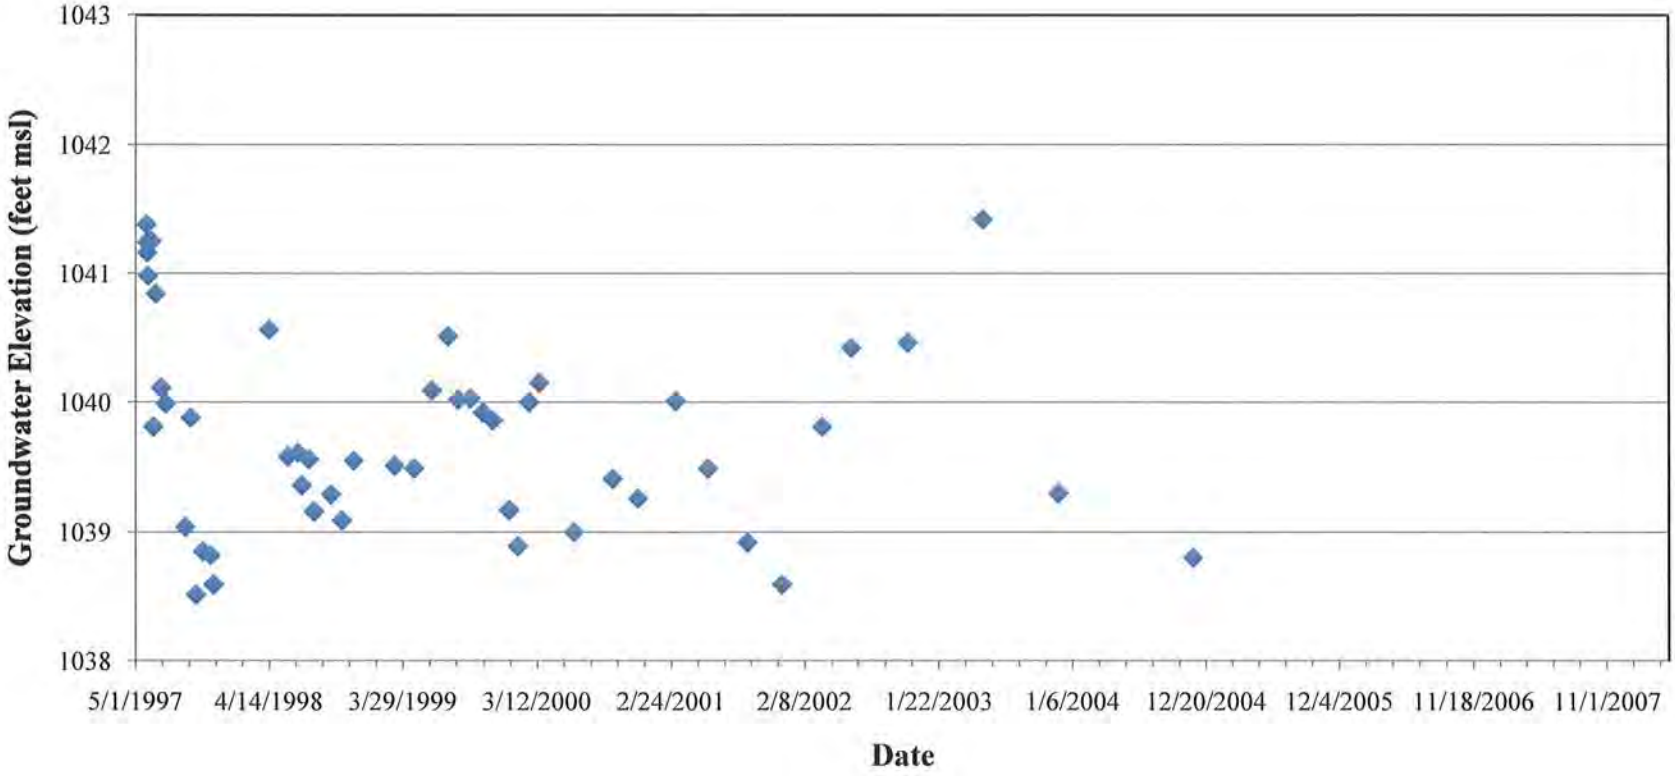
Groundwater Elevations in Well MW-1B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 86-95 Feet Below Ground Surface



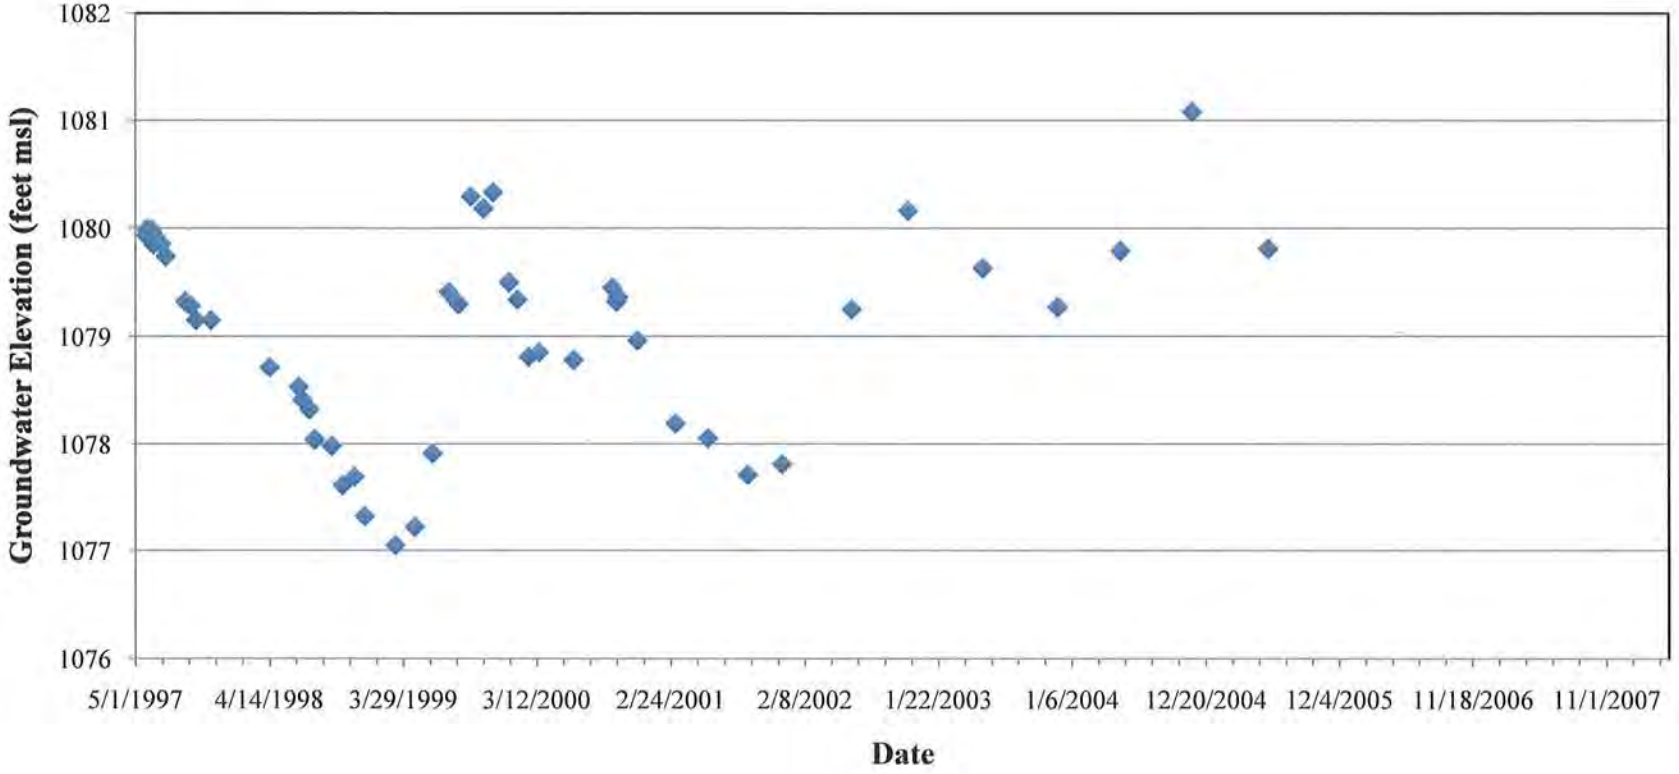
Groundwater Elevations in Well MW-2A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 42-52 Feet Below Ground Surface



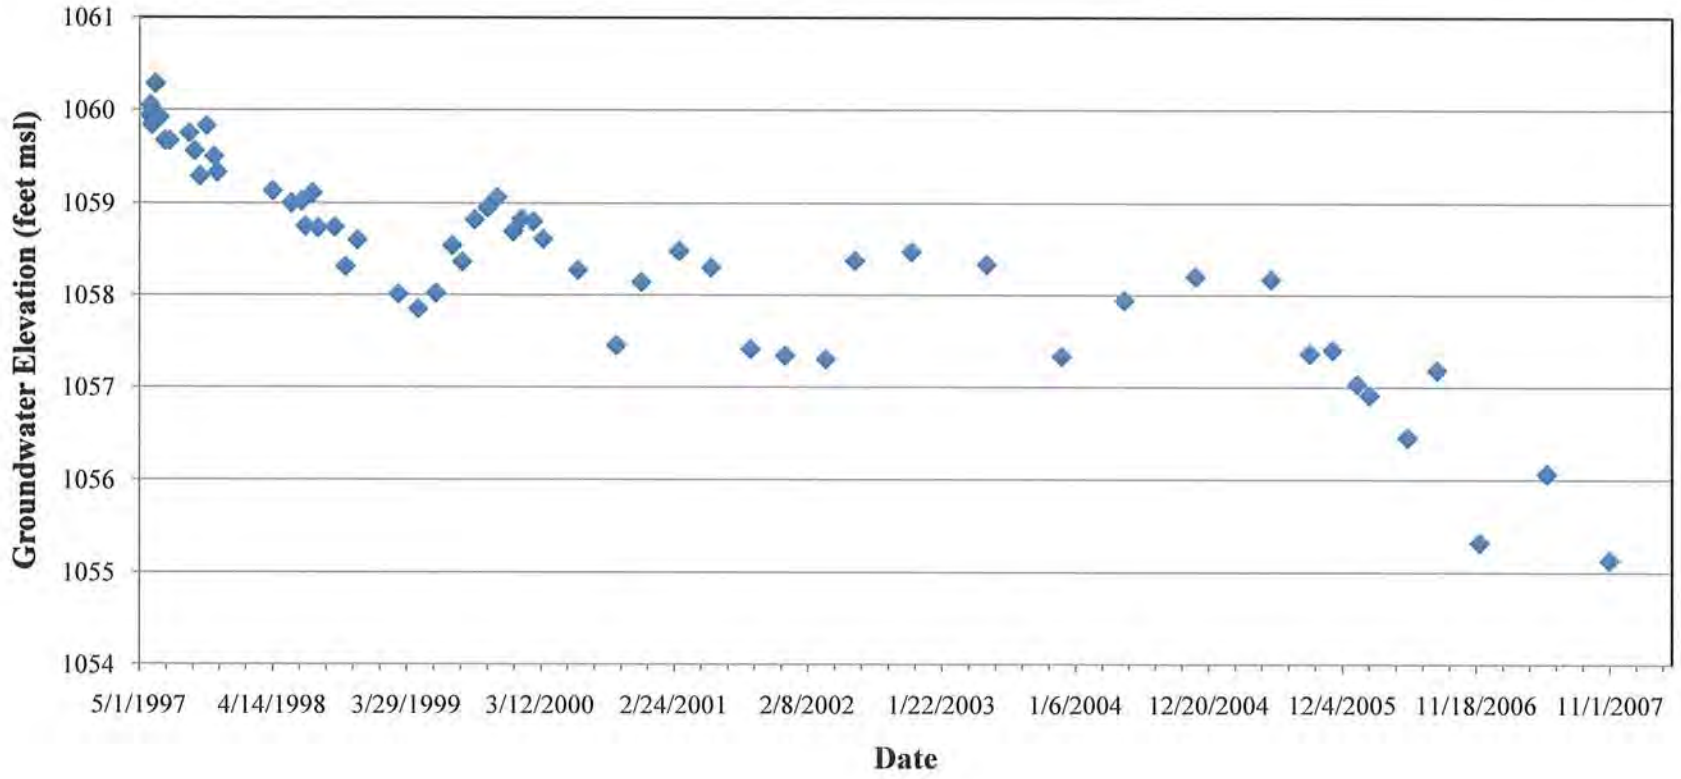
Groundwater Elevations in Well MW-2B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 102-110 Feet Below Ground Surface



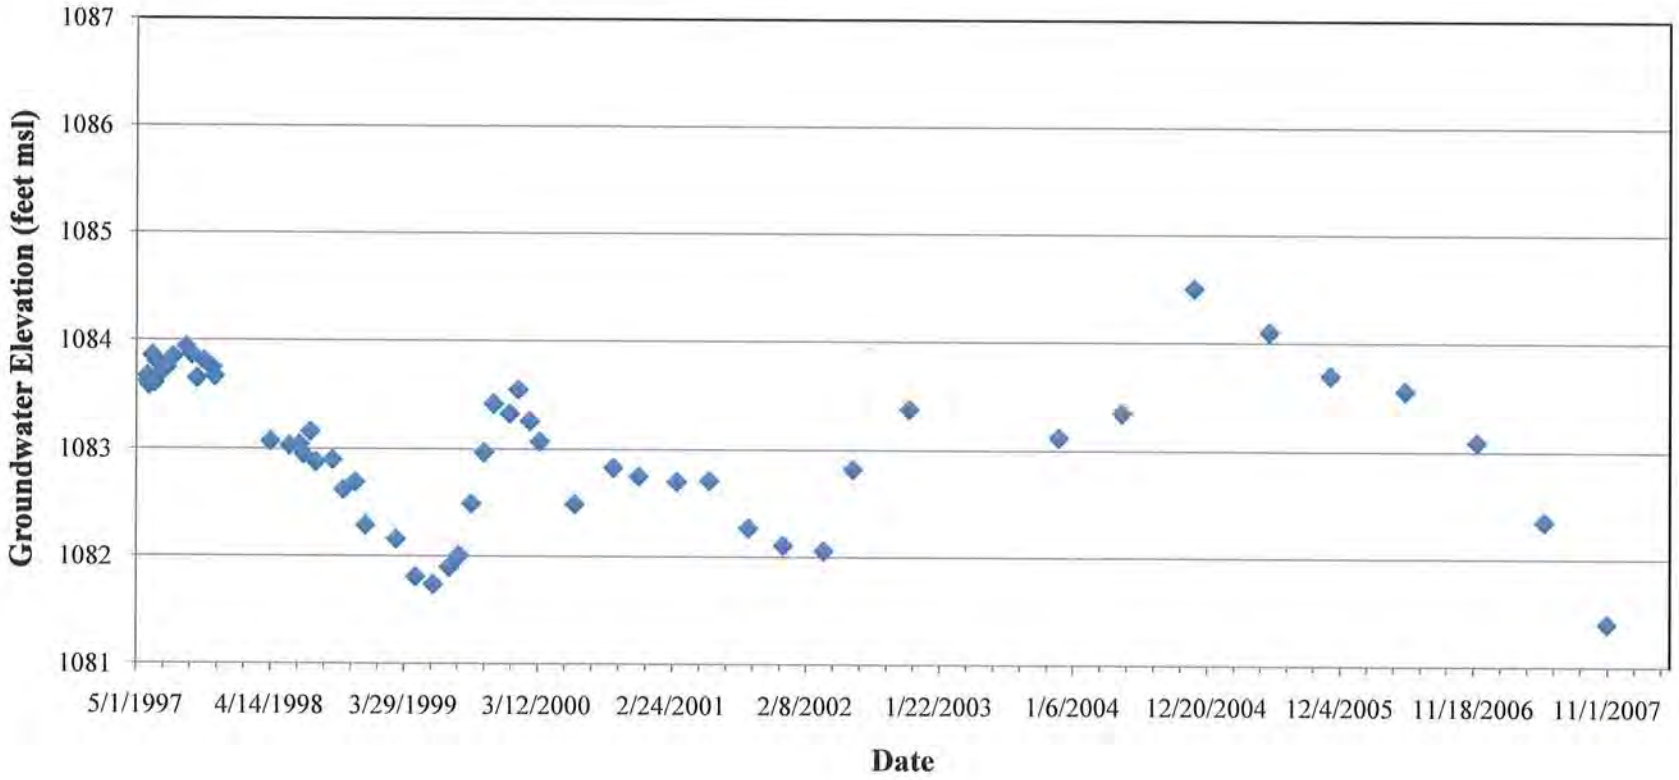
Groundwater Elevations in Well MW-3
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 42-52 Feet Below Ground Surface



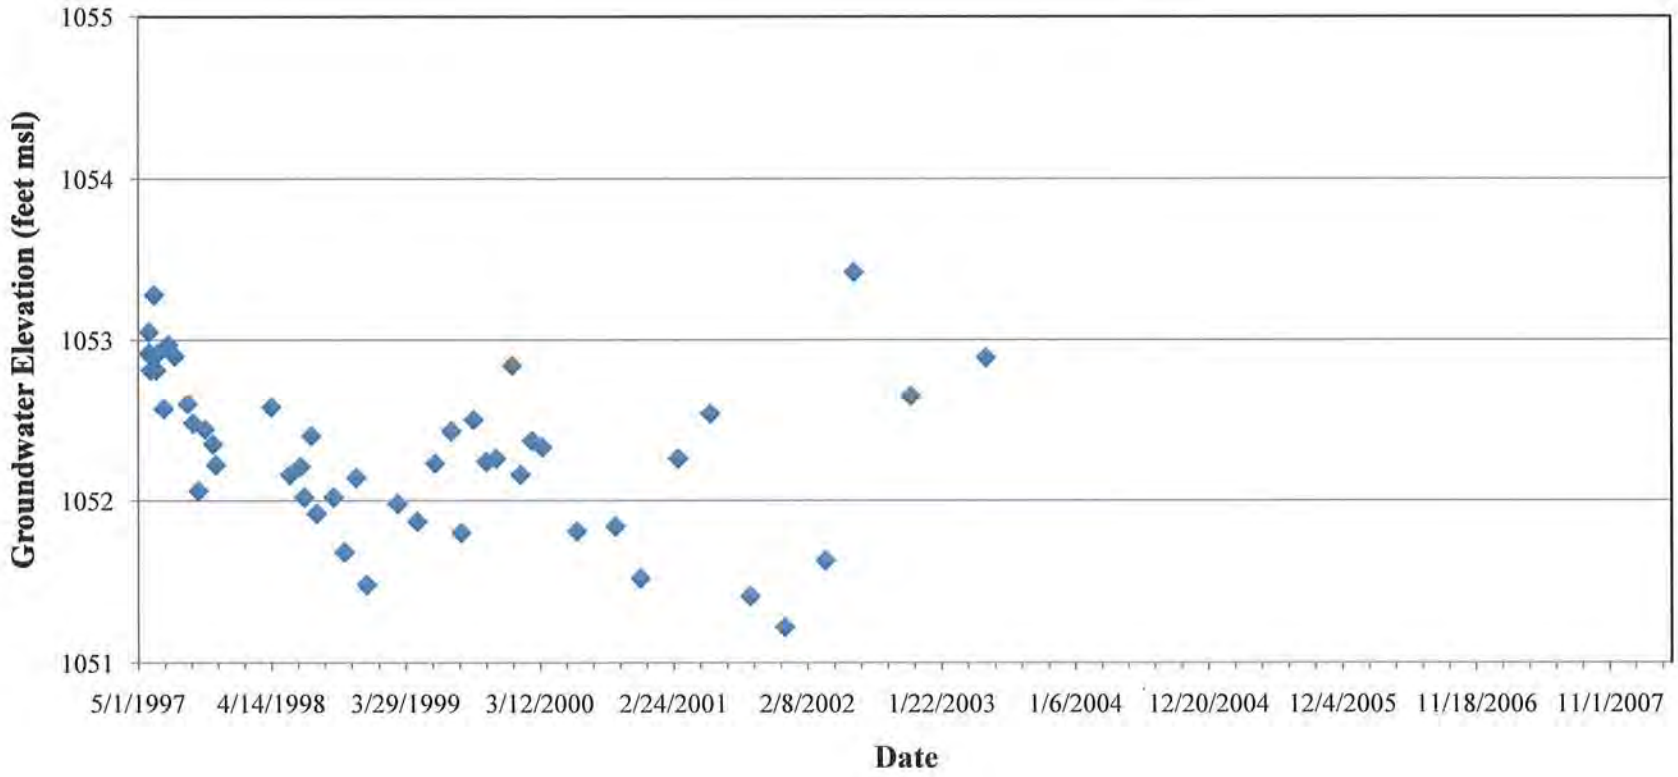
Groundwater Elevations in Well MW-4
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 80-90 Feet Below Ground Surface



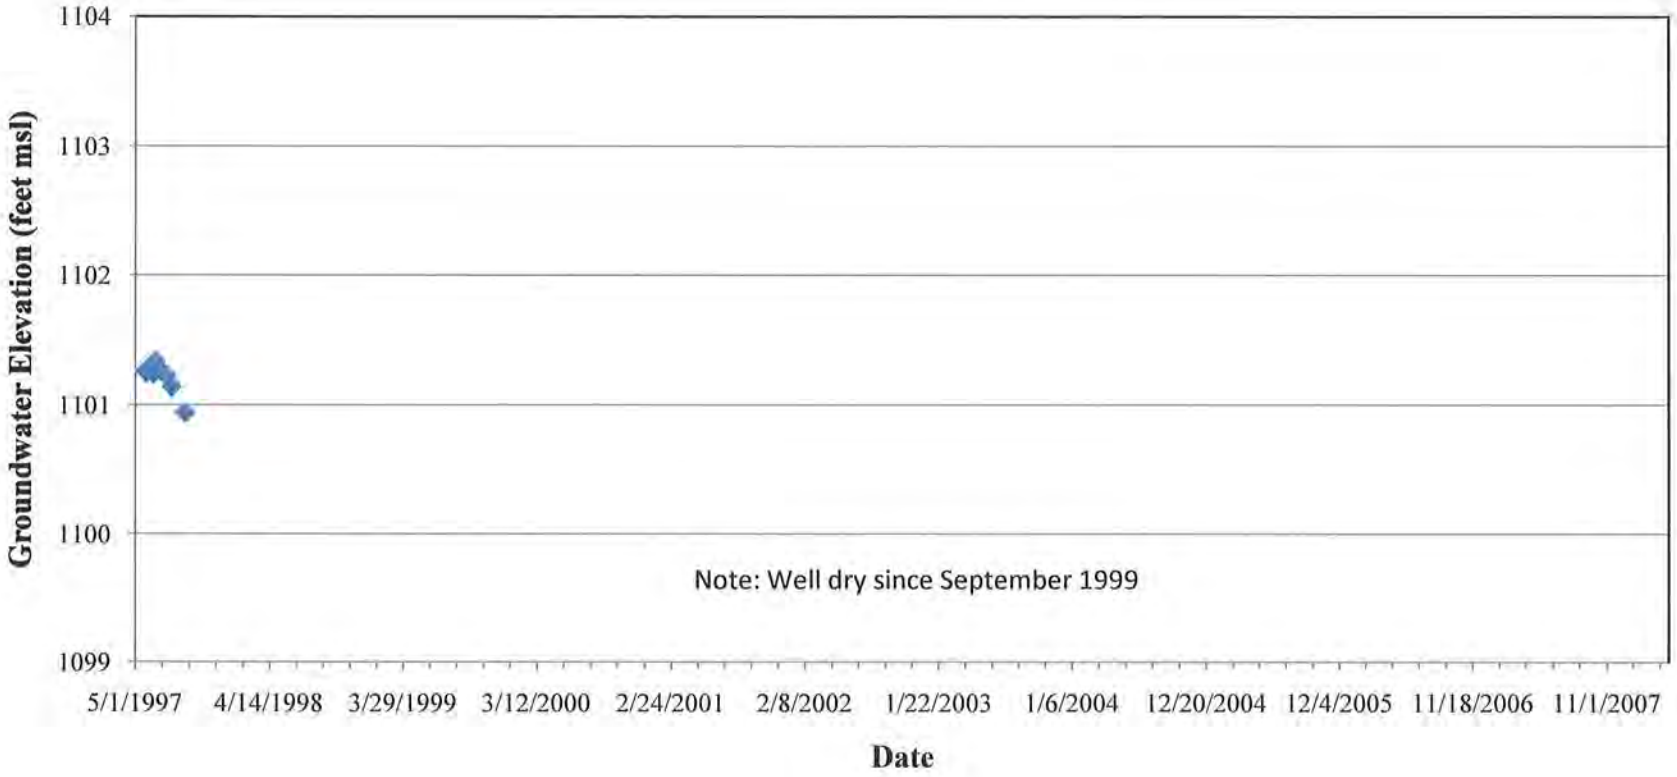
Groundwater Elevations in Well MW-5
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 83-93 Feet Below Ground Surface



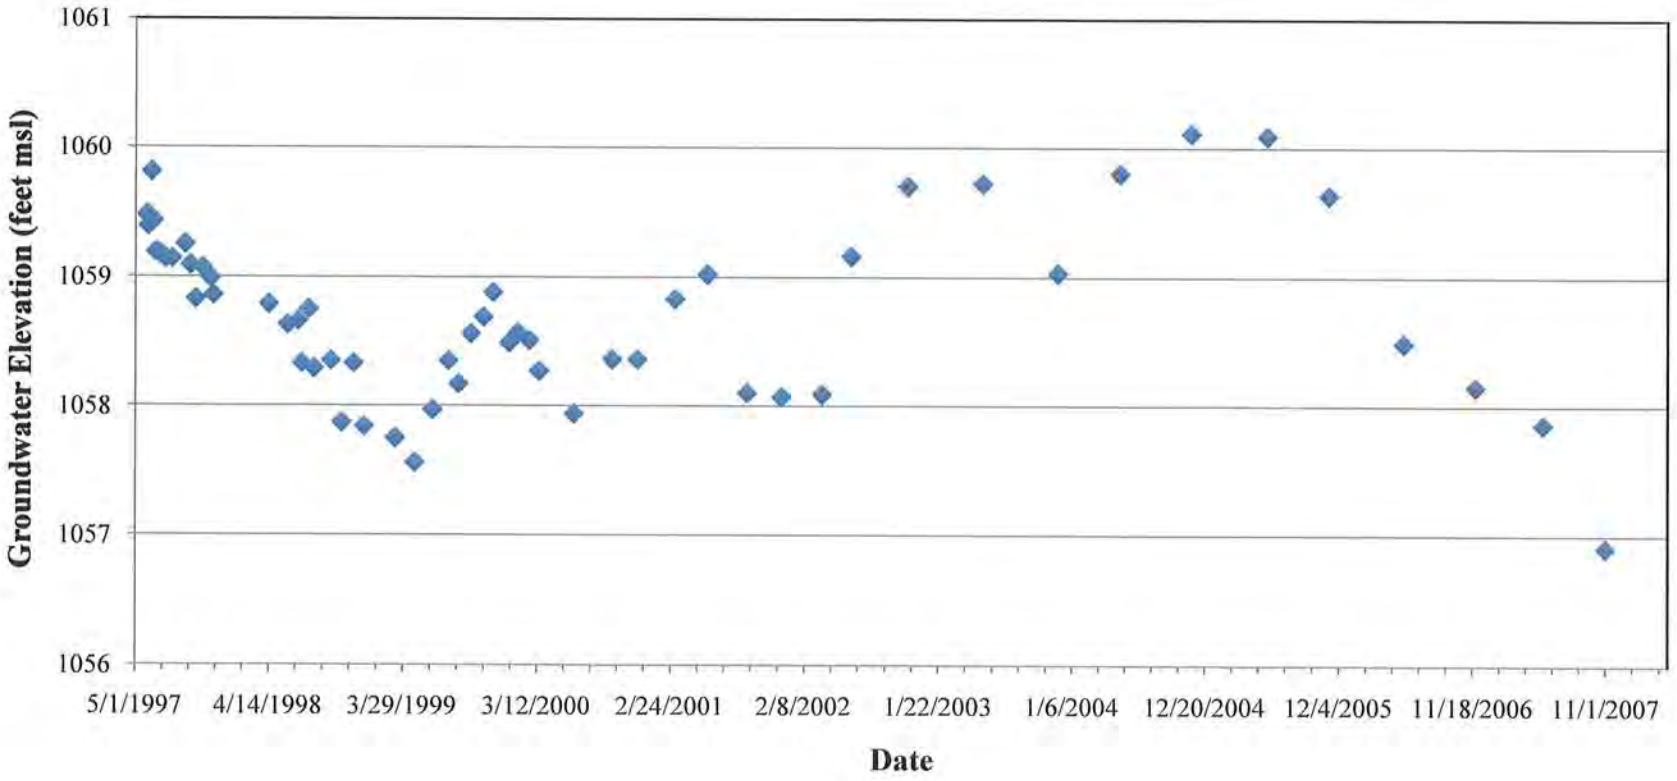
Groundwater Elevations in Well MW-6
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 111-121 Feet Below Ground Surface



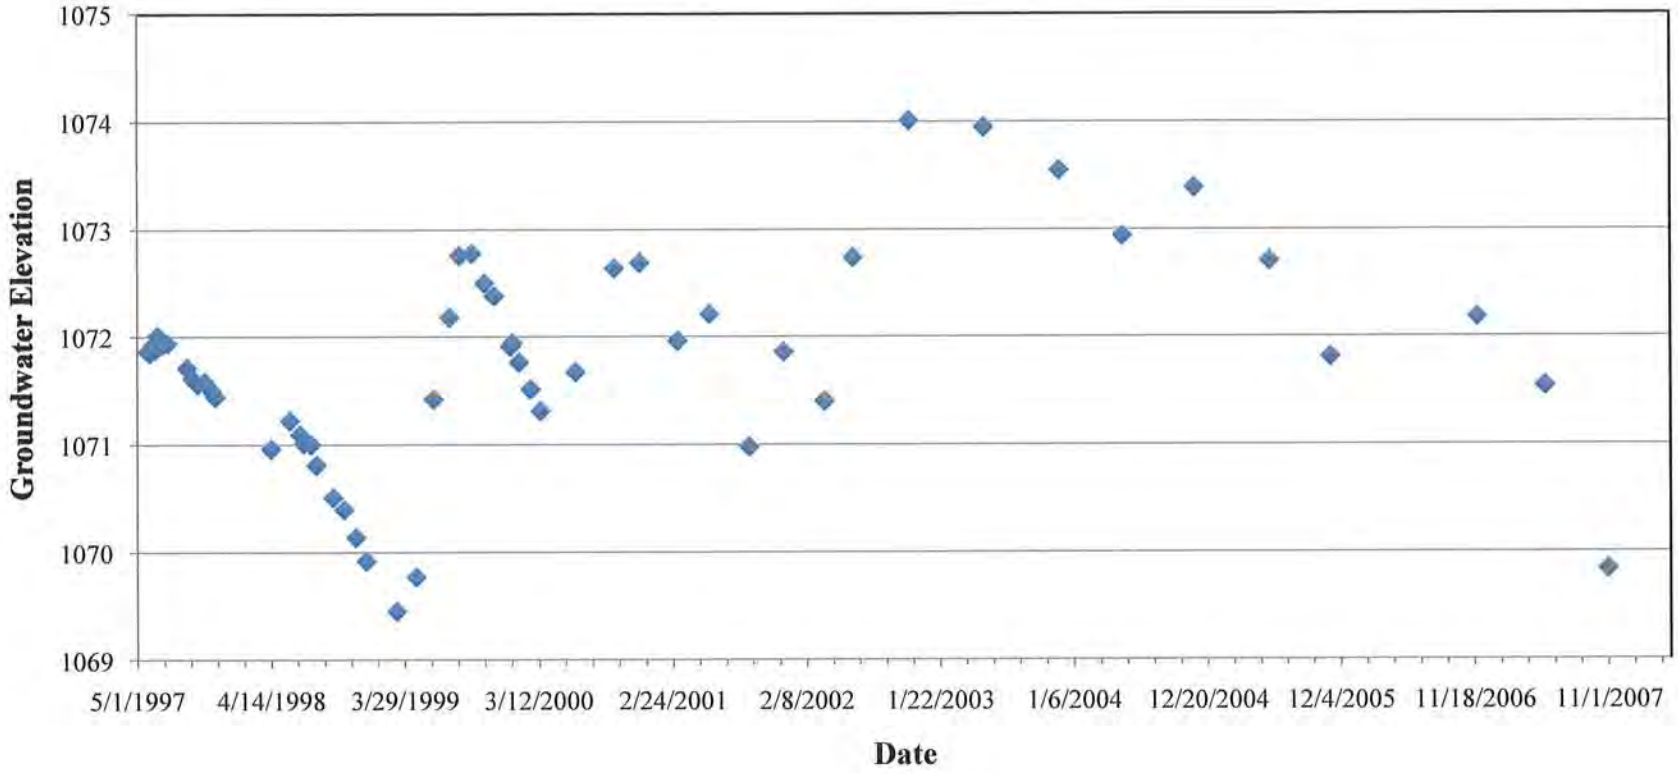
Groundwater Elevations in Well MW-7
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 24.5-34.5 Feet Below Ground Surface



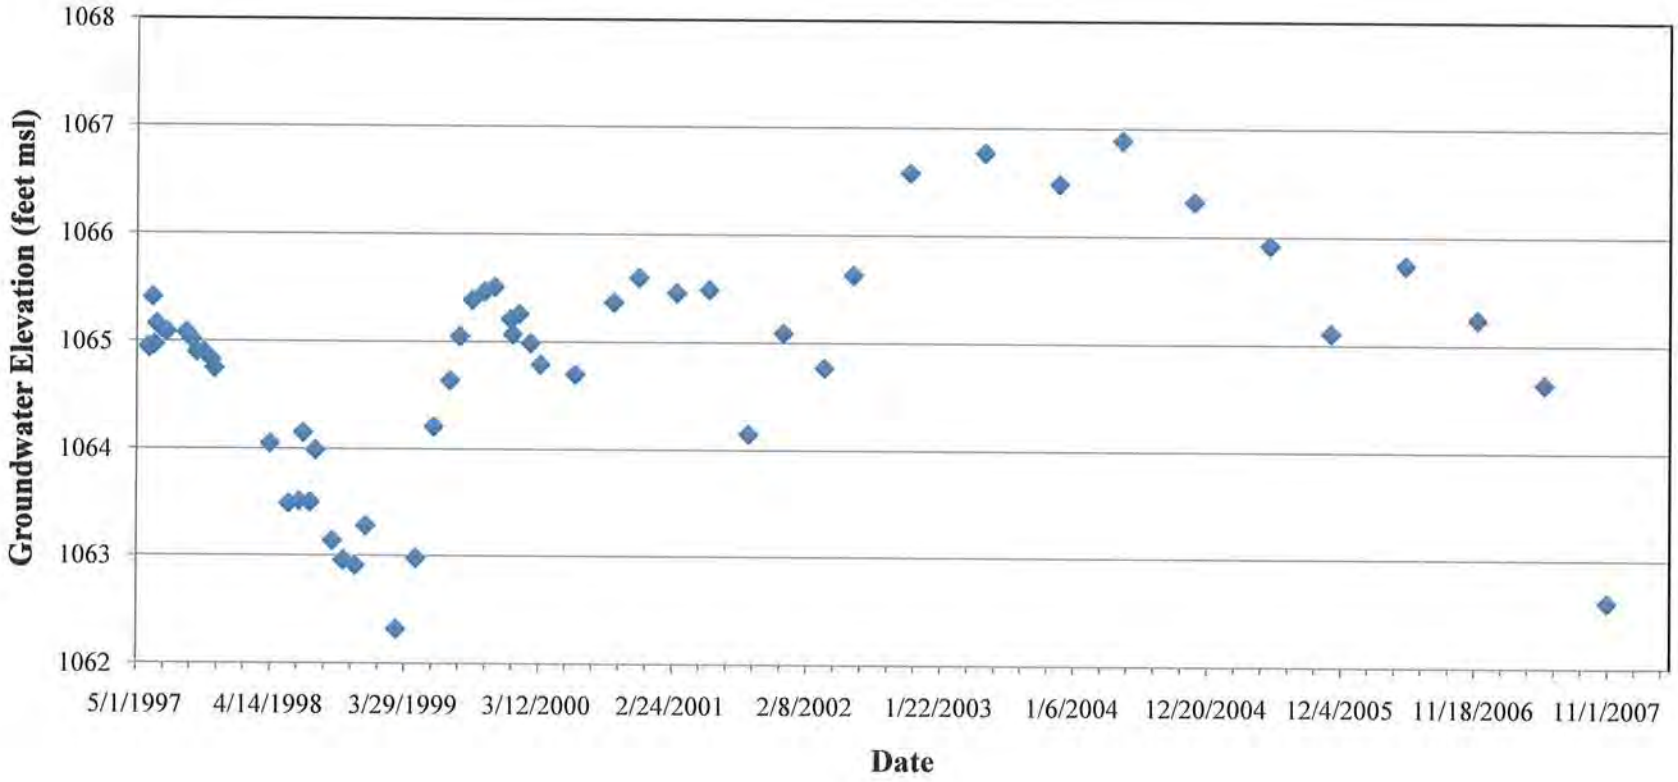
Groundwater Elevations in Well MW-8
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 133-141 Feet Below Ground Surface



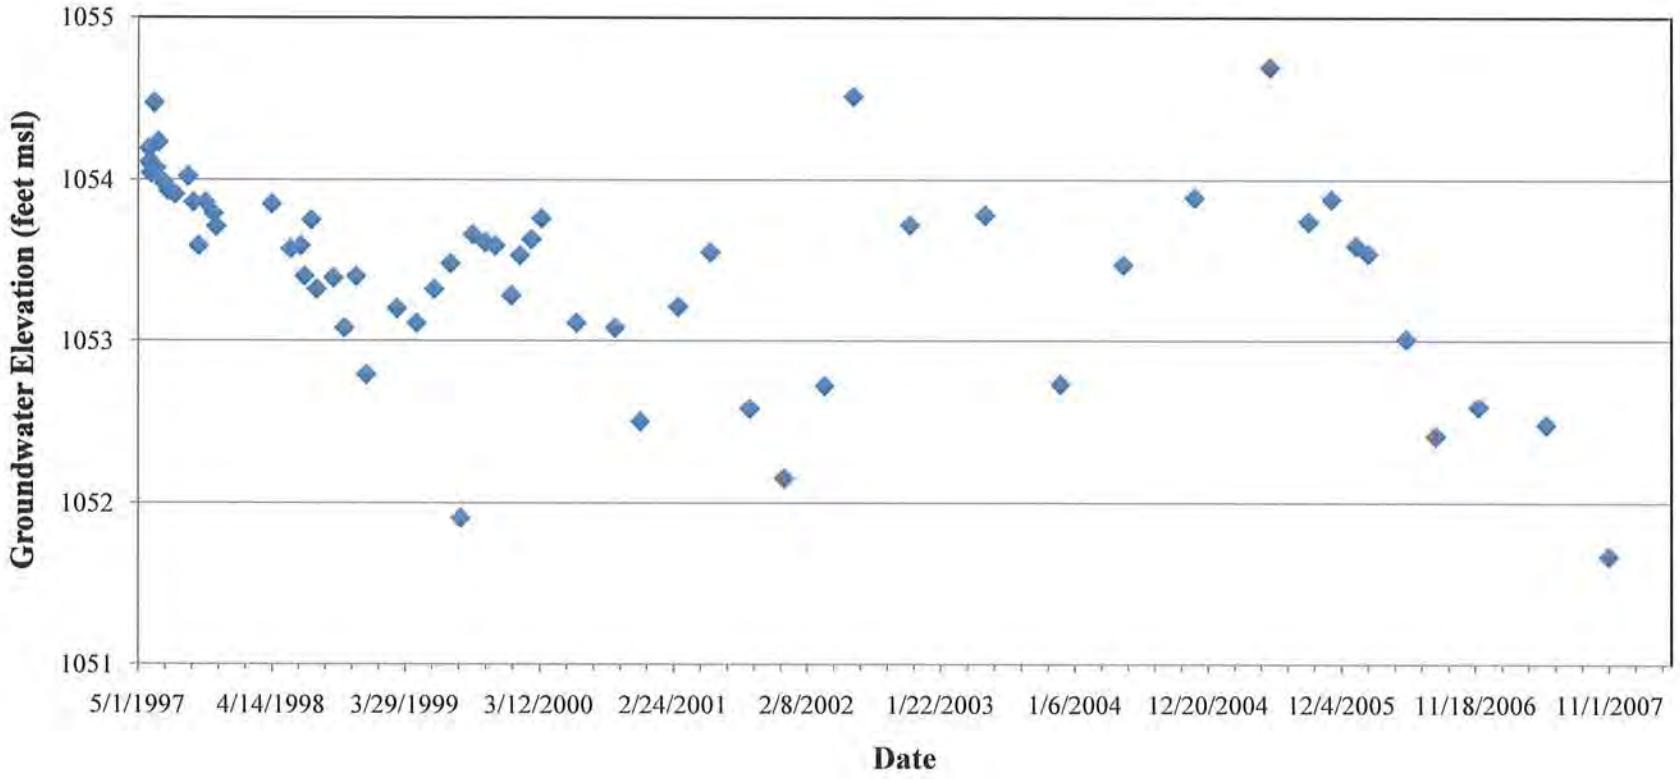
Groundwater Elevations in Well MW-9A
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 55-63.5 Feet Below Ground Surface



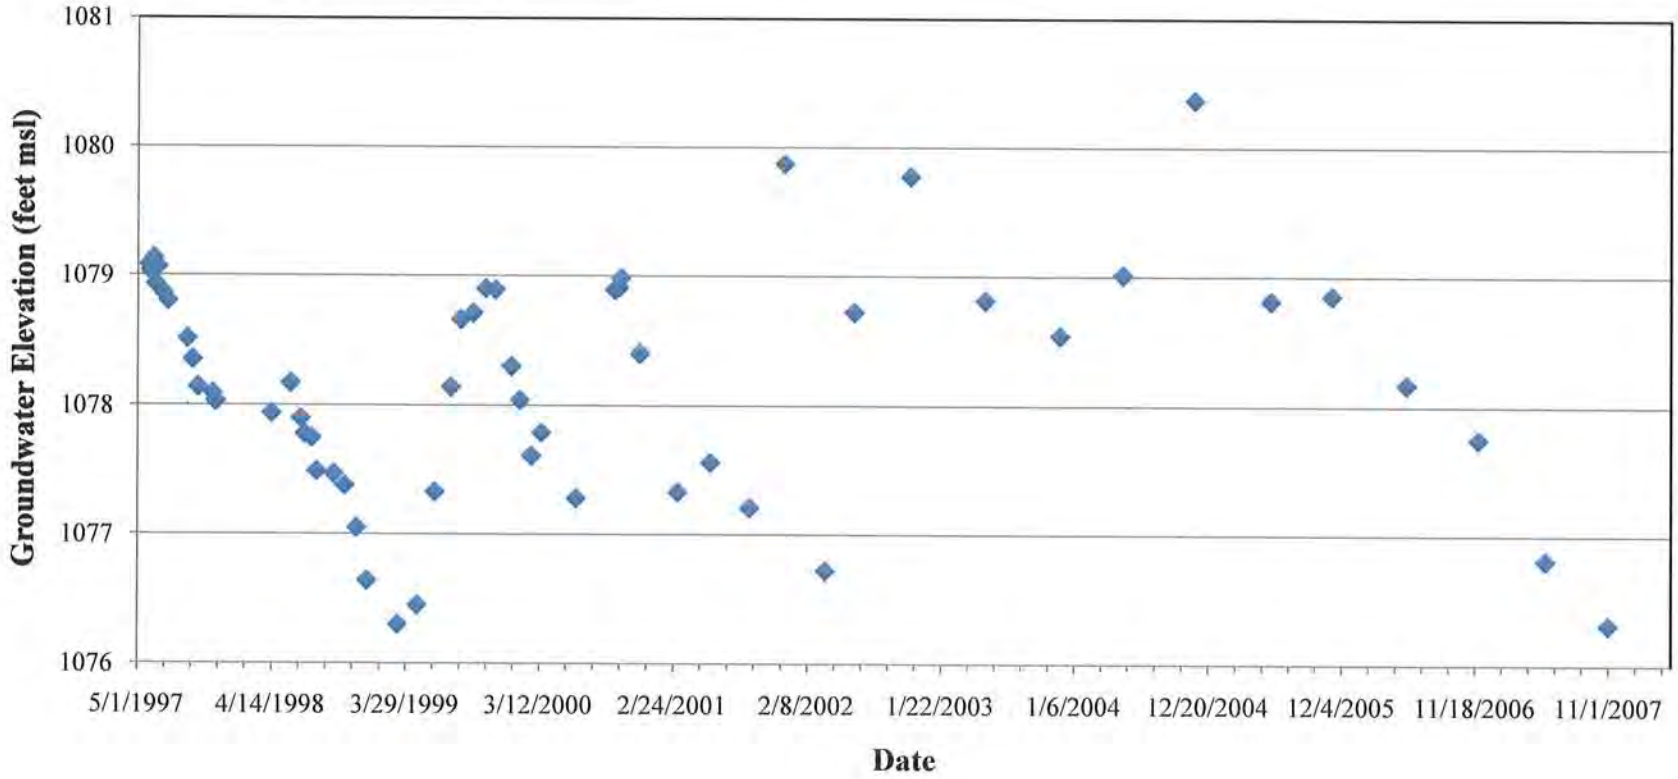
Groundwater Elevations in Well MW-9B
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 105-113.5 Feet Below Ground Surface



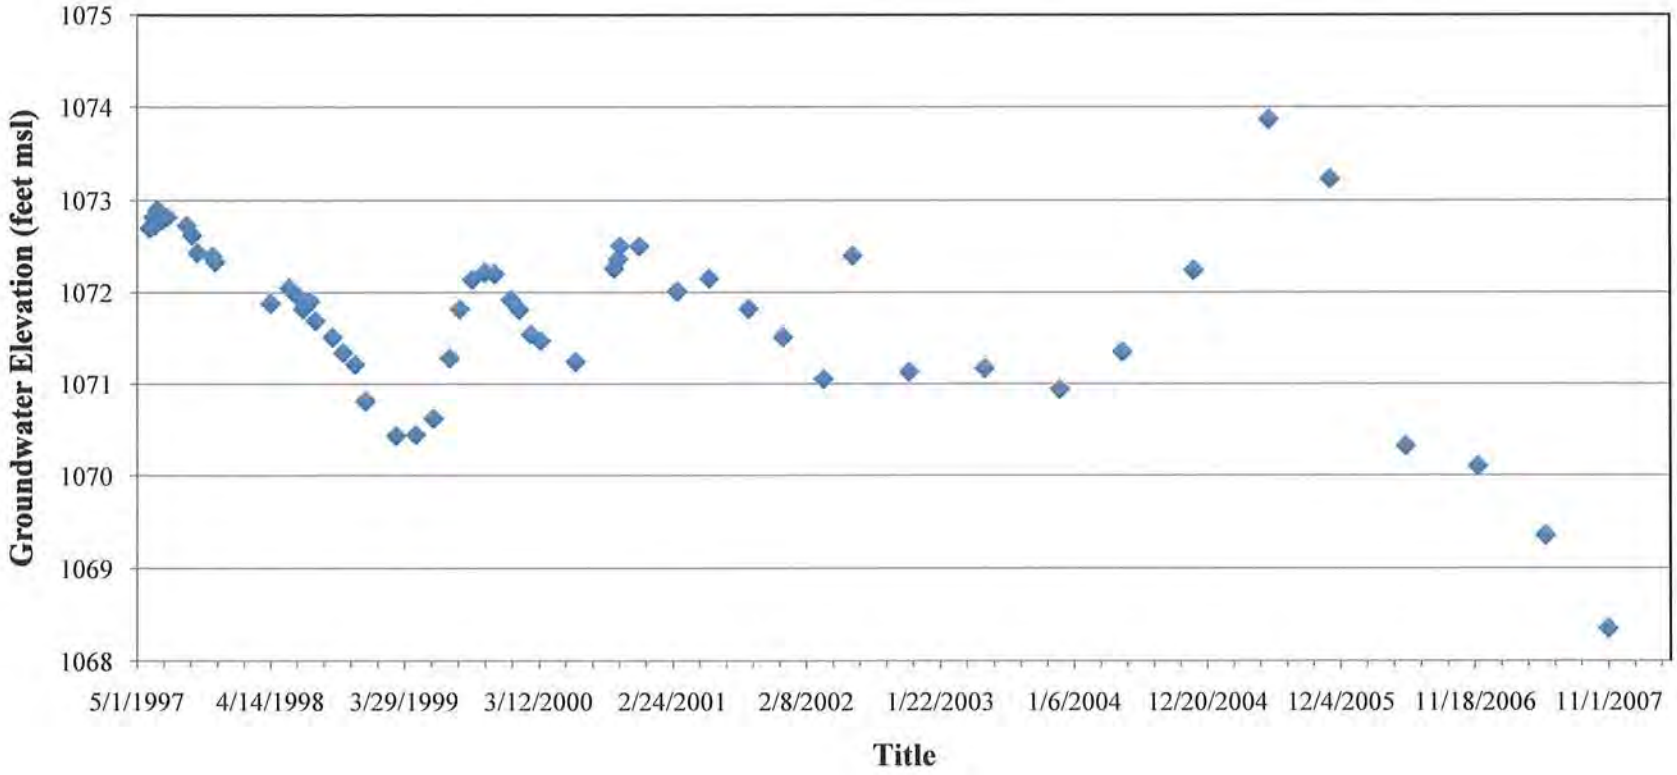
Groundwater Elevations in Well MW-10
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 92-100.5 Feet Below Ground Surface



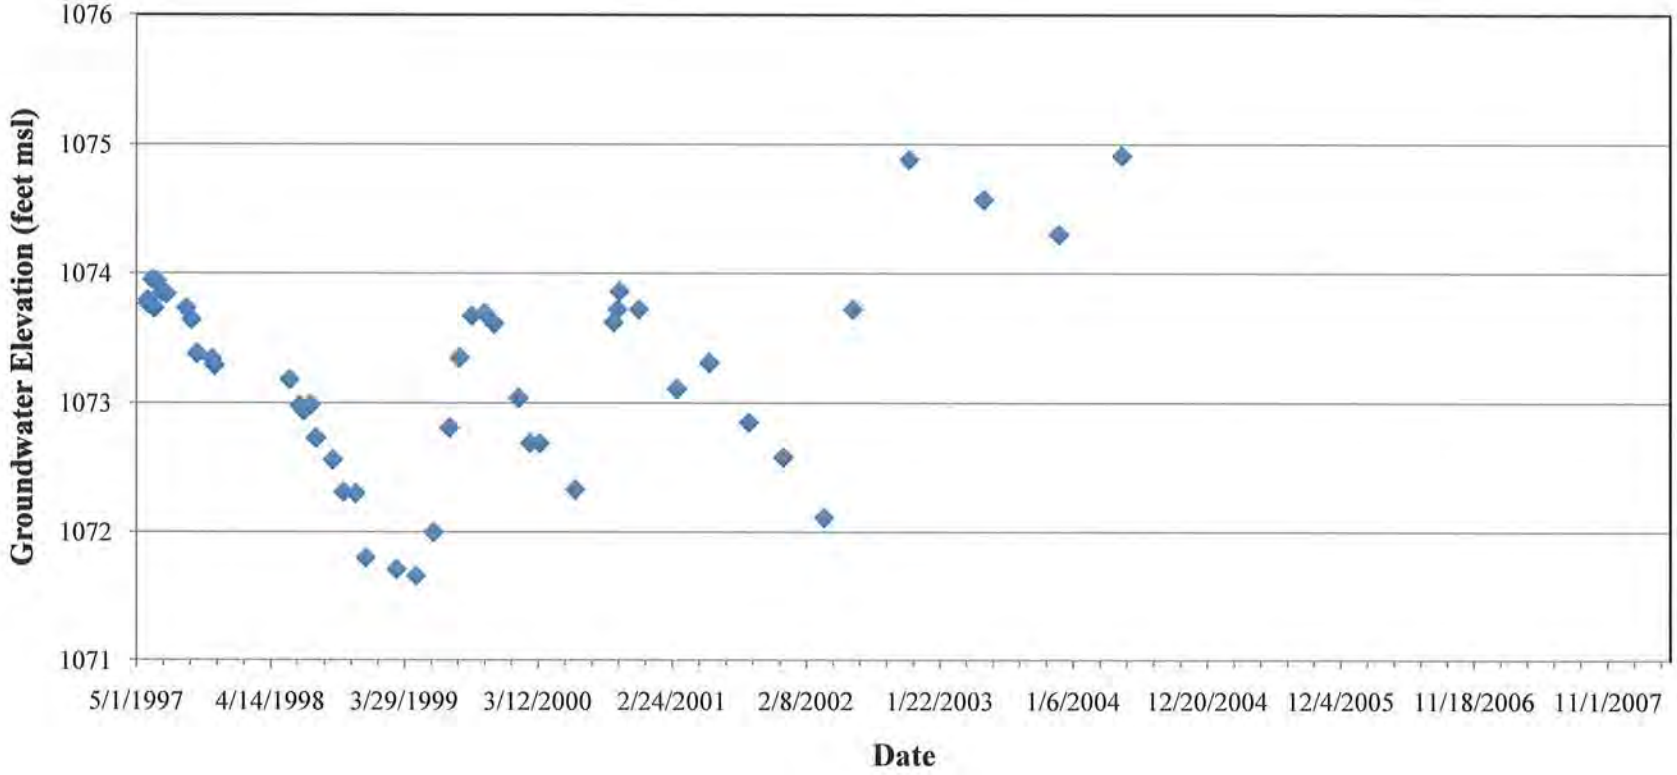
Groundwater Elevations in Well MW-96-1
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 65-75 Feet Below Ground Surface



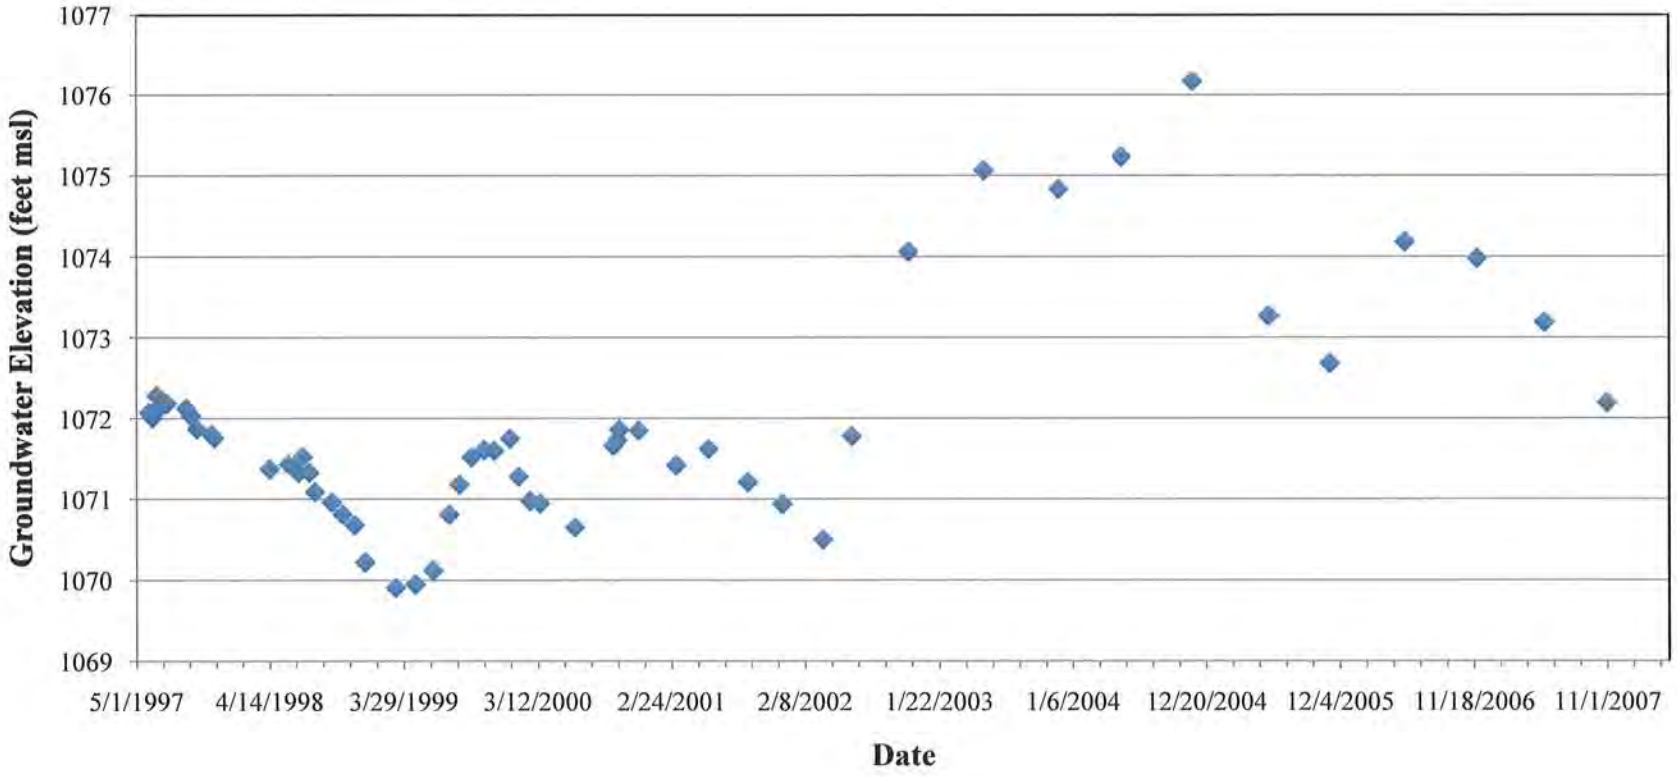
Groundwater Elevations in Well MW-96-2
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 60-65 Feet Below Ground Surface



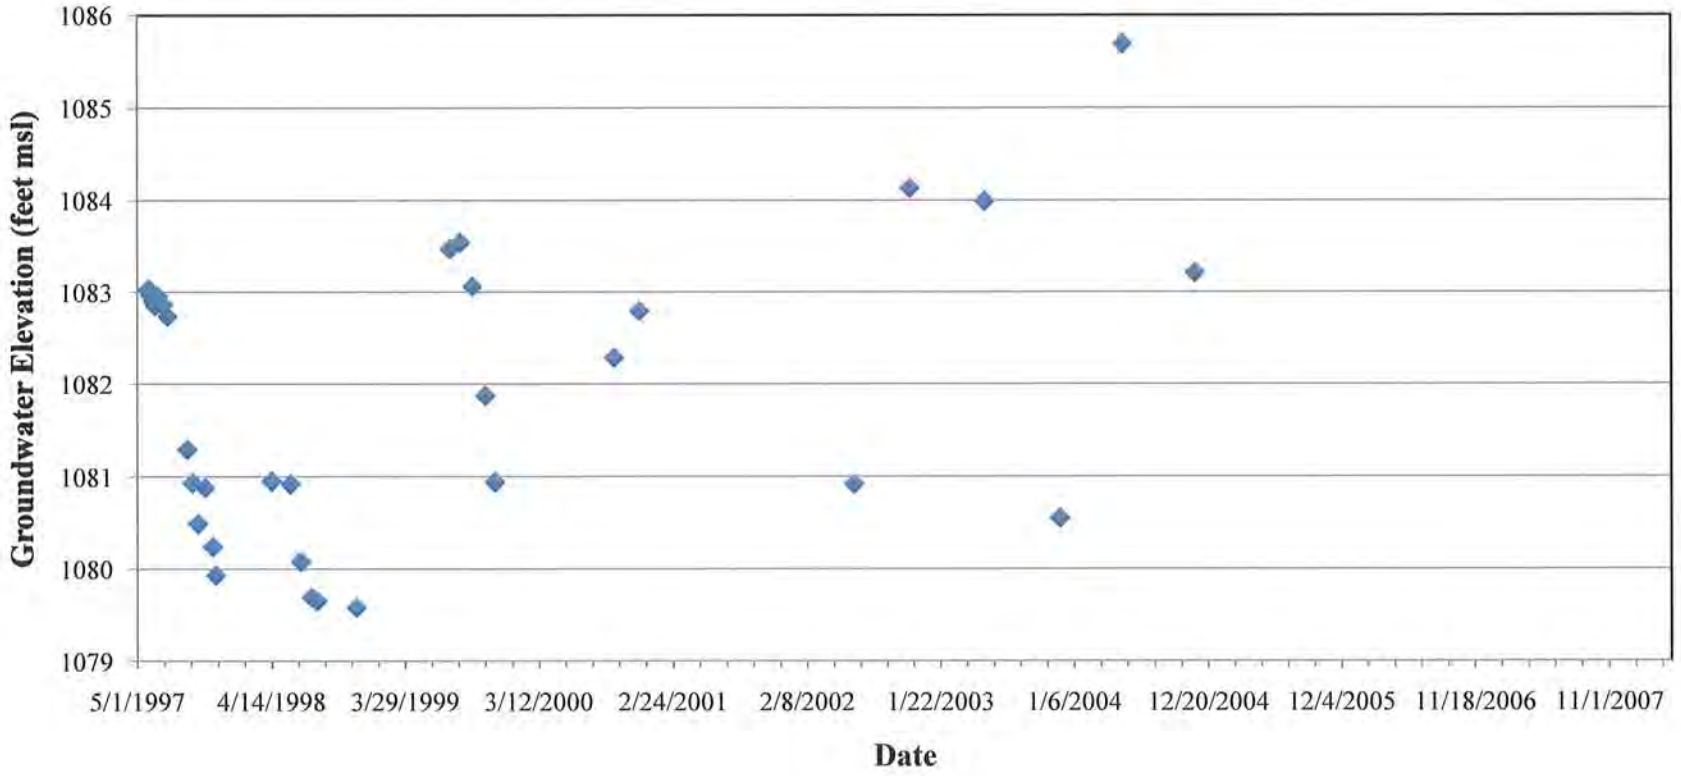
Groundwater Elevations in Well MW-96-3
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 66-71 Feet Below Ground Surface



Groundwater Elevations in Well MW-96-4
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 60-65 Feet Below Ground Surface



Groundwater Elevations in Well P-1
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 30-40 Feet Below Ground Surface



Groundwater Elevations in Well P-2
Ford/Kingsford Site, Kingsford, Michigan
Screened Interval 28-38 Feet Below Ground Surface

<	Less than detection limit.
mg/kg	Milligrams per kilogram.
A	Tentatively identified compound is an adol condensate.
B	Constituent was also detected in laboratory blank.
J	Estimated results.
N	TICs that were not reported as unknowns were qualified as tentatively identified.
